Final Cover

Final covers used in landfill bioreactors play two important roles: prevention of uncontrolled infiltration of precipitation, and trapping generated gas within the waste matrix. A final cover generally consists of a vegetative layer, a protective layer, a drainage layer, and a barrier layer. The drainage layer encourages subsurface runoff and reduces the mounding depth of moisture on barrier layer. The barrier layer could be a thick compacted clay layer or a plastic liner. Because of the potential for high differential settlement of the cell, it is more appropriate to use a flexible plastic liner (e.g., low density polyethylene or polyvinyl chloride).

Waste Degradation and Gas Production in Landfill Bioreactors

More recently, increased attention has focused on the role of CH_4 in climate change. Methane from landfills contributes a significant proportion of annual global CH_4 emissions, although the estimation is subject to a great deal of uncertainty. The global CH_4 emissions from landfills range from less than 20–70 Tg/year or about 5–20% of the total estimated emissions of 375 Tg/year from anthropogenic sources globally.

Anaerobic decomposition of organic waste in the landfill environment produces LFG. LFG mainly consists of methane and carbon dioxide, both of which are odorless. Trace constituents of other volatiles, often malodorous or toxic gases, are also found in LFG. LFG can migrate through soil into structures located on or near landfills. Since methane presents a fire or explosive threat, LFG must be controlled to protect property, and public health and safety. Also, many jurisdictions require landfill owners/operators to reduce reactive organic gas emissions to improve regional air quality. Thus, engineered solutions are needed to efficiently and safely monitor, collect, and process LFG. As noted, a positive side to LFG control is energy recovery. Today's technology allows a landfill owner/operator to recover the

energy in LFG while reducing gas emissions. Revenue from the sale of LFG or electricity generated using LFG as a fuel can offset costs for landfill environmental compliance and/or closure.

LFG is the product of microbiological decomposition of land-filled garbage. The microorganisms turn complex organic compounds in garbage into methane, carbon dioxide, and trace amounts of other compounds. The composition of LFG depends on activity of the bacteria involved, the available substrate, and other factors. Methane comprises about 50–55% of LFG, while the rest is mostly carbon dioxide. Methane is the most reduced organic molecule. In other words, no further conversions to simpler organic molecules are possible once methane has been produced. It is produced as an end product of anaerobic metabolism. Methane is a short-lived GHG with an atmospheric lifetime of approximately 12 years compared to over 100 years for carbon dioxide. It is 25 times more potent as a GHG, kilogram for kilogram, than carbon dioxide.

Considering one of the key objectives of an anaerobic landfill bioreactor is to produce the maximum amount of gas in the shortest time period, it is necessary to ensure gas production conditions are maintained at optimum levels. Apart from waste characteristics, various cell operating conditions are the main contributors to gas production. Characteristics of waste as placed in the cell, such as pretreatment of waste and degree of compaction, are critical. The relevant questions are:

- What is the effect of preprocessing the waste (opening plastic bags, etc.) on biodegradation rate of the waste? What would be the effect of reduction of particle size (to provide more homogenous waste) on biodegradation rate of the waste?
- What are the reactions rates for various combinations of feed stocks types (e.g., mixed waste, organic waste alone, organic waste, and sludge etc.)?
- Is it possible to increase the microbial populations within the waste mass to accelerate the biodegradation process? Is it necessary to introduce additional microbial populations into the landfill from sources like digested sewage sludge?

Answers to some, but not all, of these questions are available in literature. Considering the impact initial waste properties may have on other cell parameters such as waste density and permeability, answers to the above questions should not be evaluated by themselves. Questions related to waste compaction are:

- What should be the as filled waste density to ensure even distribution of leachate during recirculation?
- What is the impact of as filled waste density on settlement behavior and eventual creation of a waste density and permeability gradient within the solid waste matrix?

Because of the interrelationship of various processes, it is extremely difficult to answer these questions. Nevertheless, past experience and laboratory/field investigations have shown the following:

- Although a low compaction density aids in leachate delivery to the entire waste mass at the early stages of cell operation, waste density changes over time creating a scenario of high settlement rates, permeability gradients (high permeability in upper parts of the cell and low permeability in lower parts of the cell), and potential lateral migration and channeling of recirculated leachate.
- High rates of gas production during early stages of cell operation, usually exceeding gas production in traditional landfills by an order of magnitude or more.

Waste Settlement in Landfill Bioreactors

Waste settlement could impact landfill bioreactor operations due to the reasons identified above. Within this context, the basic questions raised are as follows:

- How does the waste density profile vary with time and space?
- What is the relationship between initial compaction density and waste settlement?
- Is preprocessing of waste and/or mixing of sewage sludge with high moisture content feasible or desirable in terms of waste settlement?
- Is there any significant effect of swelling (rebound of waste after initial compaction) on compaction/construction?
- What is the impact on stability/settlement of daily/intermediate cover? If so, what should be the most suitable cover material?
- What is the effect of waste density on lift height and total height of a landfill bioreactor?

In a typical landfill, the majority of settlement takes place over a long period of time as a result of the decomposition and mechanical compression. Settlement is often described in three stages: (1) initial compression, (2) primary compression, and (3) secondary compression. The initial compression is seldom discussed because compression happens immediately when a load is applied. However, considerable settlement during the filling phase should be included in landfill bioreactor design because it contributes to the total amount of waste that can be deposited in a cell. This settlement is typically unaccounted for and usually goes unnoticed. It is anticipated that mechanical compression is the dominant mechanism that determines settlement during construction; however, since biodegradation initiates soon after the deposition of waste there may be a contribution from biodegradation as well. The influence of biodegradation on ultimate settlement is of interest to designers but the impact of biodegradation during filling may also be valuable in landfill design since filling typically takes place over a period of several months.

Experience with Field Operations: Gas Production

Although the concept of bioreactor landfilling is relatively new, a number of demonstration anaerobic bioreactors are underway in Northern America and Europe [15]. Crow Wing County Landfill located in north central Minnesota was started in 1998 and accepted 50,000 t of waste annually in an area of 5.7 ha. More than one million liters of treated and untreated leachate were injected via horizontal laterals, working face spray, and spray on yard waste composting over intermediate cover [16]. The Burlington County bioreactor in northwest New Jersey had leachate recirculation from 2002 to 2005 in a 4 ha area accepting about one million tons of MSW. The New River Regional bioreactor was a "research" bioreactor in Union County, north central Florida. It had about one million tons of waste in-place in a 5 ha area. Leachate was recirculated into an existing interim capped landfill with an exposed membrane cover. Volume of leachate recirculated was about 24,600 m^3 [16]. The 2 ha Salem County anaerobic bioreactor in southwest New Jersey received leachate via horizontal injection trenches since 2000. The rate of moisture addition is about 0.167 m^3/t waste [16].

A hybrid bioreactor is in operation in Calgary, Alberta, Canada, since 2006. The Calgary Biocell is a unique facility where the three processes, anaerobic bioreactor, aerobic bioreactor, and mining, are sequentially applied in one cell. The Calgary Biocell is a full-scale facility, which covers an area of 100 m × 100 m with a waste footprint of 85 m × 85 m and a maximum height of 18 m. The schematic diagram of the Biocell is presented in Fig. 1. The base of the Biocell is 50 m × 50 m, and it extends 10 m below the ground surface. The shape of the Biocell is a pyramidal square frustum increasing sectional area with side slope of 3H: 1V up to ground level. The bottom liner/leachate collection systems are used to minimize groundwater contamination and maximize recovery of leachate. The Biocell received 48,000 t of residential (high in organics) and selected commercial wastes, with the resulting feedstock placed in three lifts of 5–6 m each. Collected leachate is recirculated after ensuring the quality is acceptable. A pipe system was added to recirculate the collected leachate. Recirculation of leachate adds the much needed moisture and transfer bacteria from well-inoculated waste to freshly deposited waste, thus accelerating the establishment of microbial community. The Biocell was instrumented to gather time-resolved and real-time moisture, temperature, and settlement data.

The construction of the Biocell began in August 2004 and it accepted approximately 43,000 t of waste from April 2005 until May 2006. The final cover was completed in October 2006 and the Biocell became fully operational as a landfill bioreactor in the same

Landfill Bioreactors. Figure 1
Schematic diagram of calgary biocell

month. The intermediate thin-biocovers were made up of a mixture of compost and soil with some mulch used as makeup material in some areas.

The gas production rate from October 2006 to September 2008 is shown on Fig. 2. The initial gas production rate was low. After leachate recirculation was initiated, the gas production rate increased four-fold to 254 m^3/h. Thereafter, the gas production rate decreased gradually and reached a steady state flow rate of 170 m^3/h throughout the winter months. The methane generation potential, calculated from waste composition data, is 120 m^3/t of solid waste. Hence, in October 2006 the theoretical gas generation rate at the Biocell should be approximately 282 m^3/h which is very close to the field measured value of 254 m^3/h reported in Fig. 2.

For comparison purposes, Fig. 2 includes the cumulative methane generation curve for a landfill cell containing 43,000 t of waste and operated as a dry-tomb sanitary landfill. The Scholl Canyon model was used to generate this curve using the parameter values k = 0.023 $year^{-1}$ and Lo = 116.7 m^3/t.

The parameter values are those proposed by Environment Canada for a typical sanitary landfill in the province of Alberta. Evidently, the gas production at the Biocell is more than 400% higher than that of a dry-tomb type sanitary landfill of similar size and configuration located in Calgary, Alberta.

Future of Landfill Bioreactors

Waste disposal practice has evolved over the years from open dumping to the current practice of sanitary landfilling. However, future waste disposal practice lies with landfill bioreactors, anaerobic, aerobic, and/or hybrid. However, being a relatively new technological innovation, full-scale operation of bioreactors could be fraught with uncertainties.

In addition to the unavailability of key design parameters (e.g., optimum moisture content, compaction density), a number of operational difficulties exist. Short-circuiting may occur during leachate recirculation preventing achievement of field capacity for most of the waste matrix. Head build up on liner may require innovative operational practices. Continuous pumping of leachate at two to three times the generation rate may be necessary to avoid head buildup on the liner. The use of permeable daily and intermediate covers may help in attaining field capacity but may give rise to other problems. Accelerated gas production may lead to odor problems if not accommodated by aggressive LFG collection. Leachate infiltration and collection piping are vulnerable to irregular settling and clogging. If the waste is less permeable than anticipated, increased condensate production leads to short-circuiting of moisture into LFG collection pipes. Storage must be provided to manage leachate during

Landfill Bioreactors. Figure 2
Comparison of gas production at the biocell and a conventional landfill

wet weather periods if the final cover is not impermeable. Conversely, leachate may not be sufficient in volume to completely wet the waste, particularly for aerobic bioreactors. Increased internal pore pressure due to high moisture content may lead to reduced factor of safety against slope stability and must be considered during the design process.

In view of the concerns raised here, it is clear that many questions are yet to be answered hence detailed research on different components of bioreactor landfill is required.

Future Directions

Four primary problems are associated with land disposal of solid waste, namely esthetic concerns, ground/surface water contamination with leachate, emission of landfill gas, and extensive space requirements. Over the last three decades, the design and operation of dry-tomb sanitary landfills have managed to solve, to a large extent, the first two problems. However, the last two problems have not been adequately addressed. The landfill bioreactors, especially the Biocell, are proposed to solve all four problems at the same time. The proposed holistic approach is expected to revolutionize waste management throughout both developed and developing countries.

Glossary

Closure plan The plan for closure of a landfill after it ceases receipt of waste materials.

Hazardous waste A solid waste which due to its quantity, concentration, or physical, chemical, or infectious characteristics may pose a substantial present or potential hazard to human health or the environment when treated, stored or disposed of, or otherwise mismanaged or can cause or contribute to an increase in mortality, or an increase in irreversible or incapacitating illness.

Landfill A disposal site where solid waste is buried between layers of soil and other materials in such a way as to reduce contamination of the surrounding land. The modern version of landfill, also known as a sanitary landfill, is lined and subsequently covered to keep pollutants from leaking into the soil and water.

Leachate A liquid that has passed through or emerged from solid waste and contains soluble, suspended, or miscible materials removed from such waste.

Post-closure plan The plan for the period after a landfill undergoes closure. Post-closure care activities typically include maintenance of the waste containment systems and monitoring of the groundwater to ensure that waste is not escaping and polluting the surrounding environment. In the USA, the required post-closure care period is 30 years from site closure, but this can be shortened or extended by the State Director.

Solid waste Any discarded material that is abandoned by being disposed, burned, or recycled. A solid waste can have the physical form of a solid or semisolid.

State Any of the 50 United States, the District of Columbia, the Commonwealth of Puerto Rico, the Virgin Islands, Guam, American Samoa, and the Commonwealth of the Northern Mariana Islands.

State Director The chief administrative officer of the lead state agency responsible for implementing the state permit program by the United Sates Environmental Protection Agency.

Sustainability It is defined herein as a process that resolves the conflict between various competing goals and involves the simultaneous pursuit of consensus with economic prosperity, environmental quality and social equity.

Sustainable development It is defined herein as a pattern of resource use that aims to meet human needs, at the same time preserving the environment, with the goal that human needs are met in the present and for future generations.

Definition of Subject

This section examines the sustainable reuse of existing landfill sites. Sustainability is examined in the context of the existing regulatory authority of the United States Environmental Protection Agency (USEPA). The viability of reuse is also examined in the context of planning, engineering, and environmental and economic issues. Lastly, sustainability of reuse of existing landfill sites is measured against the goals of sustainability: environmental benefits, economic benefits, and achievement of sociopolitical policies. Based upon these reviews it is concluded that the reuse of existing landfills can meet the goals of sustainability.

Introduction

With the growing scarcity of available land, especially in urban areas, the reuse of existing landfill sites has been frequently accomplished. Landfills have the benefits of filled lands and have been redeveloped for other uses after their life as a waste disposal facility has ended. The sustainability of this practice of reuse is in need of further review.

Review of Federal Regulations for Landfill Closure

As an initial step in the sustainability analysis, a review of the USEPA Regulations for landfills was completed for two types of landfills that are potential candidates for sustainable reuse: landfills that received nonhazardous waste materials and landfills that received hazardous waste materials. There is a far greater number of nonhazardous waste landfills than hazardous waste landfills.

Subtitle C (Hazardous Waste Materials)

Under the Resource Conservation and Recovery Act (RCRA), all hazardous waste disposal, including landfill disposal, is regulated under Subtitle C and its resultant USEPA regulations at 40CFR Part 264. Landfills

authorized to accept hazardous wastes must follow very stringent guidelines for their design and operation. Part 264 requires inspections, personnel training, location standards for disposal facilities, construction quality assurance, detailed facility design and operation, the use of manifests and tracking of received waste materials, preparation of contingency and emergency plans, closure, post-closure care, and extensive financial assurance. Subtitle C reserves the authority for approval of hazardous waste landfills to the USEPA. The most current version of Part 264 is July 2006.

Subtitle D (Nonhazardous Waste Materials)

RCRA Subtitle D and its resultant USEPA regulations at 40CFR Parts 257 and 258 authorize the landfills that serve as disposal sites for all wastes not regulated by Subtitle C, including municipal wastes. Waste materials authorized for disposal at Subtitle D Landfills also include household hazardous waste and hazardous wastes generated by small quantity generators.

RCRA provides a procedure so that States can be become qualified by the USEPA to assume the responsibilities for regulating Subtitle D Landfills in their states (Qualifying States). As detailed in 40CFR Part 239, this procedure entails the submission of a State Solid Waste Management Plan to the USEPA Administrator or designee. This Plan will have the following contents: (1) all sources of solid waste in the State including hazardous wastes, residential, commercial and institutional solid waste, wastewater treatment sludge, pollution control residuals, industrial wastes, mining wastes, agricultural wastes, water treatment sludge, and septic tank cleanout; (2) all aspects of solid waste management: resource conservation, source separation, collection, transportation, storage, transfer, processing (including resource recovery), treatment, and disposal; (3) established and justified priorities for solid waste planning, resources, and management, and schedules and milestones for achieving the objectives of RCRA and meeting the requirements of Part 264; (4) cover a minimum of a 5-year time period from the date submitted to USEPA for approval; and (5) an identification of the State's legal authority for solid waste management including any modifications to regulations necessary to implement Subtitle D.

Comparison of Subtitle C and D

A comparison of the design, closure and post-closure requirements for Subtitle C and Subtitle D Landfills is shown in Table 1.

This comparison indicates that Subtitle D Landfills have generally less stringent requirements. Location criteria prohibit Subtitle C Landfills in certain seismic areas, floodplains, and geologic formations. Bottom liners, leachate controls, and cover systems are more rigorous for Subtitle C Landfills. Extensive contingency, emergency, and release detection plans are also required for Subtitle C Landfills. Lastly, Post-Closure Care requirements, including financial assurance, for Subtitle C Landfills are more rigorous and provide more long-term responsibilities and liabilities for operators/owners of Subtitle C Landfills. Overall, the current USEPA regulatory requirements would serve to preclude the reuse of Subtitle C Landfills and the priority for landfill reuse would be Subtitle D Landfills.

State Adoptions of Subtitle D

To gain a better focus on the available reuse of landfills and their regulatory constraints, a detailed examination of the USEPA Subtitle D regulations was completed. These regulations are intended to provide the minimum standards for the design, operations and closure/post-closure of Subtitle D Landfills. The USEPA regulations at 40CFR Part 239 allow a State to implement the requirements of Subtitle D. Numerous states have adopted the 40CFR Parts 257 and 258 regulations. Most of these States have adopted the USEPA regulations without any change. Some States, such as California, New York, and New Jersey, have adopted additional protective requirements beyond the USEPA regulations which have been approved as part of their submittals under 40CFR Part 239 to address local concerns of their constituencies. Reuse in the States which have gone beyond the USEPA requirements will place additional issues and concerns.

A typical example of a Qualifying State is New Jersey. Through its New Jersey Department of Environmental Protection (NJDEP), the State regulates the permitting, environmental impact, design, operations, maintenance, closure, post-closure, and financial assurance for private, commercial, and municipal

Landfill Closure and Reuse of Land. Table 1 Comparison of subtitle D and subtitle C landfills

Criteria	Subtitle D landfill	Subtitle C landfill	Comparison
Seismic	New sites and lateral expansions cannot be located within 200 ft of a fault that had a displacement within Holocene period	Not located within 200 ft of a fault that had a displacement within Holocene period	No difference for new Sites; Subtitle C more restrictive for old Sites
Flood plains	Site will not restrict the flow of the 100-year flood, reduce the temporary water storage capacity of the floodplain, or result in washout of solid waste	Site located within 100 year flood plain must demonstrate no washout of hazardous waste	No difference
Salt dome	–	Waste disposal prohibited in salt dome	Subtitle C more restrictive
Liner system	Single composite liner system of two components, with the upper component a minimum 30-ml flexible membrane liner (FML), and the lower component a 2-ft layer of compacted soil with a hydraulic conductivity of no more than 1×10^{-7} cm/s	Must prevent release from Site for active life and for entire closure period; composed of top liner and multiple composite 1×10^{-7} cm/s bottom liner including 3 ft minimum thickness soil layer	Subtitle C more restrictive
Leachate collection	Prevent maximum of 1 ft of leachate buildup	Install above top liner to prevent maximum of 1 ft of leachate buildup over liner for life of liner system	Subtitle C more restrictive
Leak detection	Not required	Required between top and bottom liner to verify integrity of top liner	Subtitle C more restrictive
Groundwater protection	Groundwater monitoring required; no potential for migration of hazardous constituents to the uppermost aquifer during the active life of the Site and the post-closure care period	Ensure that the contaminants specified in its permit are not detected in uppermost aquifer beneath the Site during the active life of the Site and the post-closure care period	Subtitle C more restrictive
Run-On Protection	Prevent run-on during a 25 year design storm	Prevent run-on during a 25 year design storm	Equal
Response action plan	Not required	Set forth actions in response to leakage from the Site	Subtitle C more restrictive
Contingency plan	Not required	Minimize hazards due to fire, explosion and release of hazardous waste or constituents	Subtitle C more restrictive
Closure plan	Written plan required; must prove compliance with less restrictive Closure Protection criteria	Written plan required; must prove compliance with rigorous closure protection criteria	Subtitle C more restrictive
Financial assurance for closure	Either Trust Fund, Surety Bond, Letter of Credit or Insurance allowed with closure cost estimate; Disbursement of funds subject to State requirements	Only Trust fund allowed with closure cost estimate; Funds to be disbursed only at the order of the USEPA	Subtitle C more restrictive

Landfill Closure and Reuse of Land. Table 1 (Continued)

Criteria	Subtitle D landfill	Subtitle C landfill	Comparison
Post-closure	30 year period: Maintain final cover and leachate collection system; Monitor groundwater; Maintain and operate gas monitoring system	Minimum 30 year period, can be extended if release is detected; Maintain final cover and leachate collection system; Monitor groundwater; Maintain and operate gas monitoring system; Prevent run-on and run-off from damaging the final cover; Protect and maintain surveyed benchmarks	Subtitle C more restrictive
Post-closure use of site	No specific restriction	Post-closure use of property can never be allowed to disturb the integrity of the final cover, liner(s), or any other components of the containment system, or the function of the facility's monitoring systems which preclude post-closure reuse	Subtitle C reuse is not possible.

landfills located in the state. A landfill in New Jersey has the following closure and post-closure care restrictions:

- No person shall construct or operate a sanitary landfill without an approval from the Department of a Closure and Post-Closure Plan. Such Plan shall consist of both a Closure and Post-Closure Care Plan and a Closure and Post-Closure Financial Plan.
- The owner or operator of every sanitary landfill shall submit to the Department a Closure and Post-Closure Care Plan prepared, signed and sealed by a New Jersey licensed professional engineer to provide for closure and post-closure care of the sanitary landfill upon application for new sanitary landfill.
- The Closure and Post-Closure Care Plan shall provide for the design and implementation of the following: (1) Soil Erosion and Sediment Control Plan certified by the local soil conservation district. (2) Final cover; final cover vegetation, maintenance of final cover, and final cover vegetation. (3) Maintenance of side slopes; run-on and run-off control programs. (4) Maintenance of run-on and run-off control programs. (5) Groundwater monitoring wells. (6) A program for the maintenance of groundwater monitoring wells. (7) A program for the monitoring of groundwater in accordance with NJPDES rules, *N.J.A.C. 7:14A*, and any permit for that sanitary landfill issued pursuant thereto. (8) A methane gas venting or evacuation system. (9) A program for the maintenance of methane gas venting or evacuation system. (10) A leachate collection and/or control system. (11) A program for the operation and maintenance of a leachate collection and/or control system. (12) A program for the installation of a facility access control system. (13) A program for the maintenance of the facility access control system. (14) Measures to conform the site to the surrounding area. (15) A program for the maintenance of measures to conform the site to the surrounding areas.
- The owner or operator of every sanitary landfill shall submit a Closure and Post-Closure Financial Plan to the Department which shall set forth the costs and expenses, and establish the means for meeting those costs and expenses, associated with full implementation of the approved Closure and Post-Closure Plan.
- The Closure and Post-Closure Financial Plan shall include an estimate which details the cost of each provision of the Closure and Post-Closure Care Plan and a projection of funds that will be available from the escrow account. The Plan shall provide that no withdrawals may be made from the escrow account without the approval of the Department. A review of the cost estimate is required every 2 years and, if necessary, the Plan is to be revised.

A revised or updated Financial Plan shall be submitted on the second anniversary of the date of the Plan's last approval. Upon closure of the sanitary landfill, a detailed description of the landfill shall be recorded, along with the deed, with the appropriate county recording office. The description shall include the general types, locations, and depths of wastes on the site, the depth and type of cover material, the dates the landfill was in use and all such other information as may be of interest to potential landowners, and shall remain in the record in perpetuity. The deed shall also provide notice that any future disruption of the closed landfill shall require prior approval from the Department.

- The post-closure care period shall continue for 30 years after the date of completing closure of the sanitary landfill.

The NJDEP regulations provide for disruption of closed landfill and through this process NJDEP addresses the reuse of a landfill. Written approval for disruptions is required prior to any excavation, disruption, relocation, or removal of any deposited material. This action may or may not involve solid waste, from either an active or closed sanitary landfill. Disruptions are defined as "Minor" for the purpose of gathering and evaluating information about the landfill's environmental or physical properties or "Major" for the purpose of the construction of buildings, roadways, parking areas, and other site improvements on top of a landfill. As per the NJDEP Technical Manual on Landfill Permits, judgments regarding the impact of a potential reuse are made on a case-by-case basis dependent on the physical and environmental characteristics. This approach appears to be typical for other Qualifying States.

Closure and Reuse of Subtitle D Landfills

While the USEPA regulations restrict the design and operations of a landfill, these regulations also specify the elements of a Closure Plan. A landfill's closure plan will have a direct impact on the viability of its reuse. The USEPA-required elements of a closure plan include: (1) a description of the final cover and the methods and procedures to be used to install the final cover, (2) an estimate of the largest area of the landfill that requires a final closure during its active life, (3) an estimate of the maximum inventory of wastes disposed on-site over the landfill's active life, (4) a schedule for completing all required final closure activities and improvements, and (5) financial assurance to pay for the cost of the proposed closure improvements. The final cover system must be designed to have a permeability less than or equal to any bottom liner system, but no greater than 1×10^{-5} cm/s; have an infiltration layer of a minimum 18 in. of earthen material; and have a minimum of 6 in. of earthen material that is capable of sustaining native plant growth.

In addition to a Closure Plan, the USEPA regulations also provided for the submission of a written Post-Closure Care Plan. This Plan controls the use of the closed landfill for a minimum period of 30 years after Closure and includes the provision of financial assurance to guarantee post-closure care. Within this Plan, a description of any planned uses of the property must be provided along with their impacts on the provided financial assurance. Post-closure use of the property cannot disturb the integrity of the closure improvements or the function of the monitoring systems. However, a USEPA-approved State may allow any disturbance (reuse) if the owner or operator demonstrates that the disturbance of the closure improvements, including any removal of waste, will not increase the potential threat to human health or the environment. Therefore, the reuse of closed landfill would require a submission which supports no increase in potential threats.

Viability for Reuse of Landfills

Planning and Land Use Issues

Beyond the regulatory requirements imposed by the USEPA and the States, landfill reuse must also meet the tests of viability: planning and land use, permitting requirements, engineering and institutional controls, infrastructure, and economics. State and local jurisdictions control the use of land through master plans and zoning regulations and the reuse of a closed landfill must comply with these requirements.

A key aspect of planning for landfill reuse will be localities' master plan. Ideally, the governing master plan should integrate the overall environment for a community with needed active and passive recreation. The master plan should view landfill reuse as

providing a unique opportunity to restore former aesthetic qualities to the area, while satisfying the open space needs of the community. More intense use also increases site development costs and utility requirements which requires further consideration. The master plan should also have been developed through a visioning process to assist the community and public. It will be important to visualize the former landfill as more than a waste disposal site and to be able to look beyond the current use to the site's potential. A strong understanding of the existing conditions and reasonable accomplishments must be the basis of planning. The master plan should also create a "sustainable and livable" environment, which can meet the community's "standard of maintenance." The plan should balance site development with the protection of surrounding natural and diverse aquatic, terrestrial and wetland habitats, as well as minimize impact on the surrounding neighborhood and community. The plan should foster public–private partnerships for funding project development, sustaining use, and long-term maintenance.

The Master Plan should also have addressed a number of landfill related considerations including: the impact of settlement, impact and operational needs for landfill gas control, storm drainage, long-term post-closure care/maintenance requirements, wetland impacts, slope stability issues, and the need for a risk assessment to support a public reuse of the landfill. The lack of considerations of landfill reuse in the localities' master plan will negatively impact a planned reuse of a landfill site.

As an outgrowth of the localities' master plan, zoning regulations and ordinances will control and limit the type and character of land use that may be implemented within that locality. The zoning will set both bulk and use limits. Bulk limits include lot area, front, rear and side yard setbacks, maximum heights, maximum lot coverage and maximum floor area ratio. Zoning will define uses "as of right" (also known as permitted uses) and prohibited or non-permitted uses. A gray area between permitted and non-permitted uses, known as conditional uses, is also typically included. The reuse of landfills is likely to be controlled as a Conditional Use and would be subject to a detailed review through submission of special documentation and conduct of public hearings.

In addition to bulk and use limits, zoning typically requires compliance with state and federal environmental regulations and permitting. The localities' zoning may also impose its own environmental requirements including wetland buffers, noise/vibration limits, and air quality/permitting.

Permitting

Additional federal, state and local permits will be required for landfill reuse and will include approvals in such areas as wetlands, flood plains, air quality, and coastal zone management. These permits and approvals will have conditions of their approval that will restrict, limit and/or prohibit certain types of landfill reuses and/or designs for reuse. For example, a Section 404 wetlands fill permit issued by the United States Army Corps of Engineers (USACE) may require setbacks or buffers from the landfill due to an adjacent high level ecology. Similarly, a Title V Major Source Air Permit issued by either the USEPA or a qualifying State may require the installation and permanent operation of a flare and/or other control devices to reduce air emissions and the location and operation of these devices will limit the scope of the landfill reuse.

A typical list of required permits and approvals for a landfill reuse is shown in Table 2.

Engineering and Institutional Controls

Closure of a landfill will include both engineering and institutional controls. The engineering and institutional controls provided through the landfill's design and closure will also determine if and how the landfill can be reused. An impact analysis to these two types of controls is a necessary consideration for the sustainable reuse of the selected landfill site.

Engineering controls are structures that have been constructed as per the landfill's construction permit and are required to be maintained during the period of closure and post-closure. These controls typically include the following: leachate collection and treatment; subsurface perimeter barriers; access roads; landfill gas collection, venting, and treatment; stormwater management drains, pipes, swales, and basins, and surface caps; and erosion and sedimentation control systems. Disturbance of the engineering controls triggers regulatory review and will require a written

Landfill Closure and Reuse of Land. Table 2 Typical permits and approvals for landfill site reuse

Permit or approval name	Issuing entity	Regulated aspect
Section 404 permit	US Army Corps of Engineers	Disturbance and/or filling of wetlands or waters of the united states
Section 9 permit	US Coast Guard	Bridge crossings over navigable waters
Landfill closure/post-closure care plan	US Environmental Protection Agency (USEPA)	Approval of plan and /or modifications (if the state has not qualified by USEPA)
NPDES permit	USEPA	Liquid discharges from Landfill including stormwater and leachates (if the State has not qualified by USEPA)
Title V/New source review permit (NSR)	USEPA	Air Emissions from Landfill (if the State has not qualified by USEPA; smaller sites = NSR; larger sites = Title V)
Landfill closure/post-closure care plan	Qualifying state	Approval of plan and/or modifications
Title V/new source review permit	Qualifying state	Air emissions from landfill (smaller sites = NSR; larger sites = Title V)
NPDES permit	Qualifying state	Liquid discharges from landfill including stormwater and leachates
Soil erosion and sediment control certification	Soil Conservation District	Soil erosion
Coastal zone management approval	State	Sites that are located in or will impact coastal areas
Flood plain permits	State	Sites that are located in or will impact regulated flood plains

regulatory consent (i.e., amendment to closure/post-closure care plan, permit modifications or zoning/planning approvals) from the landfill's permitting authority(ies).

Institutional controls are nonstructural, legal documents that control access to the landfill site and/or restrict the future use of the closed landfill site. As per 40CFR 258.60 or similar state requirements, "the owner or operator must record a notation on the deed to the landfill facility property, or some other instrument that is normally examined during title search, and notify the Qualifying State Director that the notation has been recorded and a copy has been placed in the operating record." Typically, the landfill operator will use a form document, provided by the Qualifying State and then submit the completed document to the landfill localities' Registrar of Deeds. A file copy is then submitted back to the Qualifying State.

The deed notation is a perpetual notice to any potential purchaser of the property that the land has been used as a landfill and its use is restricted. The landfill owner or operator also has the option to request permission from the USEPA or Director of the Qualifying State to remove the notation from the deed if all wastes are removed from the Site.

Infrastructure

The lack and/or the need to upgrade available infrastructure such as roads, water, sewer, and electric services will impacts the viability of reuse. Suitable infrastructure will be needed to support the reuse of a landfill site. Roads, sewers, and utilities will be key factors in the reuse planning and design. For example, if an active reuse is proposed, then the condition and viability of local roads will be a critical issue. Is there a connection of these local roads to county, state and federal highways? The location and capacity of storm and sanitary sewers will need to be considered. Will new sewers or extensions to existing sewers be

required? The capacity and availability of treatment facilities for sanitary and other liquid wastes is another key factor and lack of available capacity may otherwise invalidate a potential reuse site.

Economics

Economics will also play a key role in the viability of reuse. The financial assurance provided for both closure and post-closure care will need to be examined in view of the intended reuse. A valuation of the property of an unclosed landfill and for its intended use will need to be completed. A business financial analysis to determine the return on investment and comparison to a reuse on a Greenfield (currently undeveloped) site, where environmental factors are valued higher than economic and sociopolitical factors, will also be needed.

The uniqueness, size and complexity of the landfill reuse will usually cause significant implementation costs. Accurate cost estimates for the purposes of capital budgeting, grant application, and determining project phasing and limits are important. A long-term maintenance program should be established in conjunction with the required post-closure care program. Annual operation and maintenance costs should be developed for consideration of the site use and development.

Full or partial funding of the landfill reuse through state and federal grants should also be factored into the economics analysis. Due to the size, location and regional significance of the site, the landfill may qualify for open space and /or economic development grant funding.

Sustainability Review for Reuse of Landfills

The final step in the process is a review of Sustainability. Sustainability is a process that resolves the conflict between various competing goals and involves the simultaneous pursuit of consensus with economic prosperity, environmental quality and social equity. As coined by the Brundtland Commission, sustainable development is a pattern of resource use that aims to meet human needs, at the same time preserving the environment, with the goal that human needs are met in the present and for future generations.

The Sustainable development review for reuse of landfills is completed in three constituent parts: environmental sustainability, economic sustainability and sociopolitical sustainability. Within the environmental sustainability review, the landfill reuse is viewed against the standard of maintaining a naturally pristine environment and the avoidance of an unsustainable situation where consumption of natural resources exceeds the speed of replenishment. The economic sustainability review measures the landfill's reuse against the added economic value in relation to the landfill's aggregated ecological impacts and resource use. Similar to the environmental sustainability review, the sociopolitical sustainability review examines the relationship between the added value of the landfill reuse and its sociopolitical impacts. Positive and negative sociopolitical impacts of landfill reuse are quantified and measured against the goal of minimizing negative sociopolitical impacts. Based upon the results of this three part review, a determination that the landfill reuse is or is not sustainable development is completed.

For a landfill to be sustainable for reuse it would necessitate that the landfill either be removed or reused in such a way that it would appear that the landfill never existed following its useful life. The most important aspect would be whether or not the landfill is used to dispose of hazardous or nonhazardous wastes. Subtitle C Landfills, where hazardous waste was disposed, would not be sustainable for reuse since current USEPA regulations preclude their use for any other purpose following closure.

Throughout the landfill's useful life, sustainability would require that any resource it produces, like the generation of methane gas or as a source of solid fuel for properly designed energy producing machinery, be utilized to its maximum potential. Following, the depletion of these beneficial byproducts of land filling, any adverse impact upon the environment needs to be eliminated and the site used as it would have been prior to land filling. In this manner the definition of sustainability as "using a resource so that the resource is not depleted or permanently damaged" is preserved.

To preserve the sustainable character of a piece of property used to support a landfill use would require that the landfill's operations, resulting products, and post-closure uses promote favorable environmental, economic, and sociopolitical aspects as it relates to human interaction.

Environmental Aspects Related to Sustainability

Environmental impacts of the proposed use of the site for land filling have the greatest effect upon whether or not it is sustainable. Hazardous materials disposed of throughout the landfill and adverse environmental impacts upon the underlying soil, surrounding air quality and upon the groundwater beneath the site would, by definition, render the use non-sustainable. Therefore, this discussion focuses upon nonhazardous landfills such as municipal solid waste landfills, nonhazardous sludge landfills, and construction and demolition debris landfills.

For landfills constructed prior to the age of environmental awareness and the realization that non engineered landfills have a negative impact upon the environment, their resultant negative environmental impacts may or may not be able to be corrected. These environmental corrections would be required so that the site can be transformed into a sustainable use. Landfills that have severely impacted the various environmental media surrounding the site may require complete excavation, redeposition of waste, and the remediation of underlying soils and groundwater to remove the damage caused by the construction of the landfill that has rendered it non sustainable. Other older types of landfills may be remediated or contained in situ in order to prevent the impacts of future adverse pollution from decomposition and generation of leachate and gases. These measures could include the capping of a closed landfill and other engineering controls to collect and manage produced gases and to minimize and control the introduction of moisture into the landfill thereby minimizing leachate generation. Other measures can include the construction of impermeable barrier walls, with leachate collection systems, to prevent the escape of pollutants already impacting the environment, thereby containing them and collecting them so that they may be treated and rendered inert. Gas collection systems may be constructed to collect gases that are generated by the decomposition of the wastes. The gases can be utilized to run generators to produce energy thereby saving other natural resources for later use. The landfill gases may be cleaned of impurities and placed into natural gas pipelines for use as a heating fuel. The gases can also be destroyed in a controlled manner so that they are not emitted into the atmosphere exacerbating current unacceptable greenhouse warming concerns causing an adverse impact on the environment. These types of landfills require a longer remedial period of time to convert the site back to an environmentally neutral sustainable use.

Landfills that have been developed at present and in recent time are constructed in a controlled manner subject to strict USEPA regulatory mandates outlined in the Code of Federal Regulations under Subtitles C and D discussed elsewhere within this Chapter. Subtitle C regulations apply to hazardous waste landfills and are excluded as a part of this discussion.

These newer landfills have engineered designs that consist of discrete cells with double lined enclosure systems, upper and lower bottom liners, with leachate collection systems, to enable the collection of or recycling of generated leachate. The liner systems contain leak detection measures to alert the operators of a potential breach of the bottom liner enclosure system. The landfills are constructed with intermediate caps during operation to collect generated gases, to minimize external infiltration into the landfill and to control vermin and other vectors. Some bioreactor landfills are equipped such that collected leachate may be recirculated back into the waste mass to enhance the decomposition of the waste allowing decomposition to occur in the least amount of time. This process increases the air space of the landfill and allows more waste volume to be deposited in the landfill over a shorter period of time when compared to bioreactor landfills not subject to recirculation. When waste deposition within a cell is completed capping systems are engineered, designed and constructed to minimize infiltration and collect the gases produced during waste decomposition for beneficial reuse or destruction.

Depending upon the type of landfill that is being closed, the time required for post-closure operation and maintenance will vary. Older landfills will require longer periods of time to utilize and decompose the wastes within its confines due to the restrictions that its original construction design or lack thereof, places upon the use of decomposition enhancing recirculation techniques. Landfills that were designed and engineered using today's more advanced regulation and engineering controls would likely require less post-closure operation and maintenance. Landfills of this type would meet the definition of environmental sustainability.

Economic Aspects Related to Sustainability

The costs related to engineering a landfill so that it can be considered sustainable would ultimately cause the fee to dispose of waste to increase when compared to the tipping fees charged when landfills were unregulated. These initial costs would be necessary to provide funding for closure and post-closure operation and maintenance. Although these costs appear to be significant compared to former costs for disposal, the cost in avoided environmental damages to health, wildlife, and adjoining properties would render this increase insignificant in comparison.

Properly controlled, engineered and constructed landfills will enable a greater volume of waste to be placed within the landfill when compared to older non sustainable landfills. They can also result in the development of sources of renewable resources such as natural gas and solid fuels that can be utilized to produce heat, steam, and electricity. These renewable sources were formerly wasted because they were not collected or utilized for other purposes. The collectable quantity of landfill gas can be enhanced and its production time increased by recycling generated leachate throughout the waste mass. Although the actual amount of gas that the waste can produce is theoretically finite, the length of time required to produce that finite quantity can be reduced significantly in sustainable landfills. The remaining less decomposable solid material within a sustainable landfill may be used to operate resource recovery facilities that can produce electricity and steam. The economic benefits related to these aspects of land filling have increased in recent times due to the rising costs and depletion of our natural resources.

Sustainable landfills can ultimately be transformed into usable land suitable for construction and alternate uses. Recycling of leachate can shorten the time required for complete decomposition of the waste and the ultimate reuse of the site in construction. Once the waste is decomposed its behavior as a structural foundation material can be better determined. A highly decomposed waste reacts to applied stresses in a manner similar to that of natural soils and its behavior under imposed loading can be better predicted. This enables sites to utilize more economical construction means to support required roadways, utilities, sanitary sewer systems, drainage systems, etc., and, in some cases, foundations. The ultimate economic benefit is that the structures cost less to build and result in additional taxable sites.

Sociopolitical Aspects Related to Sustainability

Since sustainable landfills can be reused for many other purposes the affect upon sociopolitical aspects can be enormous. Initially, the control of environmental hazards related to non-sustainable land filling measures, by itself results in a better quality of life for surrounding communities. Air quality and odor concerns would be minimized during operation and would no longer be a concern following closure. Underlying sources of groundwater for potable uses would be preserved. Vermin and unwanted pests would be replaced by desirable forms of wildlife and enhanced wildlife habitats thereby improving the quality of life for nearby residents.

In rural areas and areas in many developing nations where sources of energy are limited or too far away to be utilized, sustainable landfills can provide a renewable source of cheap energy. These areas can benefit by utilizing the gases generated by the decomposition of the wastes to heat their homes, pump their water, improve their sanitation and sanitary waste systems and run their machinery.

Potential Sustainable Reuses

General

This section further examines several post-closure development scenarios that may be considered for possible sustainable reuse. As discussed in the preceding sections, landfill reuse must consider diverse criteria ranging from state and federal landfill regulations, local master plan considerations and zoning ordinances, and state and federal land use permitting issues (e.g., flood plain restrictions, wetlands, threatened and endangered species, and coastal zone management).

The intended reuse must be protective of all engineering controls and not degrade or impact post-closure operations and maintenance requirements. Furthermore, the post-closure redevelopment must satisfy the design, performance, or operational requirements and criteria that are specific to the intended

reuse. The following discussions are intended to highlight some of the major issues that should be considered for several possible sustainable reuses. Detailed studies, constraint evaluations, and engineering analysis are needed to fully quantify whether a candidate sustainable reuse is a viable post-closure redevelopment option.

Energy Generation Considerations

A closed landfill may represent a potential site for sustainable energy generation. In addition to the unique requirements and constraints that are specific to the different technologies, there are factors and considerations which are common to all energy generation technologies. The most common energy generation technologies involve electricity derived using solar, wind, or landfill gas.

Energy generated at a closed landfill may be utilized in several ways. The concept of sustainability is optimized if a long-term power supply is made available to a dedicated end-user. However, several factors must be considered to confirm that this option is technically and economically viable:

- *Infrastructure*: A transmission system is necessary for a customer to utilize energy generated at a landfill. To avoid the cost associated with the design and construction of an extensive power distribution system, the end-user should ideally be located proximate to landfill/energy distribution site. In the event the end-user is located offsite, a more extensive offsite transmission system may be required and at least a portion of the transmission system would be located on-site.
- *Permitting*: In addition to the state and federal permits and approvals associated with the redevelopment of a closed landfill, additional permitting and approvals would be required for the offsite portion of a transmission alignment. These may include the procurement of easements and rights-of-way and environmental permits such as wetlands disturbance.
- *Offsite Distribution*: Consideration should be given to the possibility that the distribution of energy to an offsite end-user may satisfy the definition of a regulated utility which may, in turn, require additional permitting and/or licensing.
- *Operation and Maintenance (O&M)*: Even if the end-user is located on-site, the energy generation and transmission systems will essentially function as localized, dedicated utility. Life cycle O&M of the energy generation and transmission systems will be required.
- *Reliability*: All of the alternate power sources share a common concern regarding reliability. Assuming an end-user requires uninterrupted electricity, back-up measures such as the use of emergency generators or connection to the local utility may be necessary.
- *Economics*: The capital and long-term costs associated with the design, permitting, construction and O&M of the generation and transmission systems must be compared to the costs associated with purchasing power from the local utility.

In the event energy generated at a closed landfill cannot be used by a local, dedicated end-user, the power may be purchased by the local utility. In order to sell power to the local utility, it will be necessary for the alternative energy developer to enter into a power purchase agreement (PPA) with the local utility. The considerations associated with infrastructure, permitting and O&M would also be applicable to this option.

Solar Energy

The generation of energy through the use of photovoltaic (PV) panels is increasingly promoted as a sustainable post-closure landfill redevelopment alternative. Some of the issues to be considered are summarized below:

- *Landfill Orientation*: The functionality of PV panels is optimized when placed in a south-facing orientation. Ideally, the landfill should be oblong with the long axis oriented in the east-west direction.
- *PV Panel Technologies*: The predominant PV panel technology currently in use is crystalline. Crystalline panels are generally considered to be the more efficient with respect to energy generation. Crystalline panels have been in use for several decades. Thin film PV panels have been recently introduced as an alternative to crystalline panels. At present, thin film panels are generally less efficient than

crystalline panels and do not share a demonstrated history of usage and reliability.

- *Panel Support*: Ground-mounted crystalline PV panels are typically supported by a relatively light weight metal frame. Because the foundation should not penetrate through the landfill cover, the metal frame may be supported on concrete ballast pads which are placed on the surface of the landfill cover. The ballast pads must be designed to prevent punching through the cover system while, at the same time, be able to resist uplift forces during periods of high winds. There is less experience regarding the use of thin film panels on landfills. One mounting system uses a backing membrane. The thin film panel is mounted to the backing membrane which, in turn, is bonded to the landfill cover geomembrane. Other mounting systems under consideration involve the use of mats or panels which are, in turn, placed on the landfill surface and secured using anchor trenches.
- *Space Requirement*: Depending on a number of factors, from 3 to 5 acres are required to produce 1 megawatt (MW) of electricity using crystalline panels. The film panels are somewhat less efficient and will therefore require greater available area.
- *Surface Drainage Considerations:* A solar energy system typically covers a significant area; however, the design of landfill mounted PV panels must assure that proper surface water management systems are not adversely impacted. The landfill surface water management components are generally designed for semi-pervious, grassed surfaces. However, because of the surface area required to generate solar energy, the impervious surface area of the landfill can significantly increase. As a result, the surface water management components (e.g., ditches, swales, down chutes, and detention ponds) may need to be redesigned and enlarged to accommodate the higher peak storm flows resulting from the increased impervious surface area. Existing erosion control measures may require modifications to safely accommodate the increased overland run-off velocities.
- *Protection of Existing Features*: Both crystalline and thin film PV panels are area-intensive technologies. The design and construction of solar energy facilities must be protective of existing features and engineering controls including: active and passive landfill gas well, access roads, surface water management systems and groundwater monitoring wells.

Wind Energy

In addition to the use of PV panels, the generation of energy using wind turbines may be a sustainable reuse of closed landfills. Some of the issues to be considered are summarized below:

- *Location*: The wind turbines must be located in an area of reliable wind. Studies are required to confirm that reliable minimum wind velocities and durations can be expected.
- *Space Requirements*: A wind turbine can produce up to 1.5 MW of electricity. However, a wind turbine facility requires a significant land area. The structures are large with rotor diameters up to 250–260 ft and the rotor hub may be located up to 260 ft above the ground. As a planning tool, each wind turbine requires approximately 0.4 acres (wind turbine plus supporting infrastructure) and a spacing of 5–10 turbine diameters is required between adjacent turbines to enable the turbines to operate efficiently.
- *Permitting*: In addition to other required environmental and land use permits and approvals, permitting of a wind turbine facility may require a bird mortality study in the event the landfill is located in a bird migratory path or flyway.
- *Foundations*: The foundation systems needed to support a large wind turbine must resist high shear and moment forces. Landfill materials are relatively loose and weak and cannot be relied upon to provide the necessary support. As a result, it is likely that the foundation loads must be transferred through the landfill mass to underlying competent bearing materials. A pile foundation system is one method of supporting the foundation loads. However, piles would need to penetrate through the bottom of the landfill. This would likely be prohibited if the landfill was constructed with an engineered bottom liner/leachate collection system. If the landfill was not constructed with a bottom liner system, it may be necessary to demonstrate that the use of piles would not result in vertical cross-contamination of the groundwater.

Landfill Gas Energy

Energy generated from the active extraction and combustion of landfill gas (LFG) is a proven technology. The installation and operation of active LFG wells would serve as a major component to control both LFG migration and odors. Factors to consider are discussed below:

- *LFG Generation:* The generation of LFG which can be reasonably extracted for energy production would extend over a finite period of time. As a result of the methanogenic process, peak LFG flows will generally occur after closure and will then decrease exponentially over time. There are several LFG generation models that can be used to estimate the LFG generation curve. Information regarding LFG generation calculation methods can be obtained from the USEPA's Landfill Methane Outreach Program (www.epa.gov/landfill).
- *Energy Utilization:* Two alternatives for the use of the collected LFG would depend on the available local infrastructure. Typically, the collected LFG is used as a fuel for specially designed engines for on-site energy generation. Issues specific to the on-site energy generation have been previously discussed. In the event the appropriate infrastructure is located nearby, it may be possible to remove impurities so that the conditional LFG can be used as low or medium BTU fuel to supplement natural gas.
- *Condensate*: Condensate will form as the relatively warm LFG is cooled in ambient environmental conditions. The condensate resulting from the cooled LFG must be collected, conveyed and managed in a manner compliant with applicable state and federal regulations.
- *Contingencies*: Even properly operated and maintained LFG engines must be taken out of service for repairs and maintenance. As a result, the LFG-to-energy system should incorporate measures to accommodate these contingencies. These measures may include spare LFG engines and/or flares which can be activated when production LFG engines are taken out of service.
- *Other Considerations*: The LFG extraction system would comprise an engineering control measure that would supplement and interact with other engineering controls. The LFG system will require electrical power and control systems; penetrations through the final cover system; monitoring and reporting; and operations and maintenance procedures. The costs associated with these considerations should be considered in the initial planning and design phase.

Post-Closure Development

Reuse of a closed landfill for post-closure vertical development has involved several end-use scenarios. Relatively passive developments have included parks, athletic fields, and golf courses. More aggressive end uses have included entertainment, retail, and residential facilities. Some of the issues to be considered with respect to post-closure development of a landfill are discussed below:

- *Closure Cover*: The post-closure redevelopment can be designed and constructed after the final closure cover is designed, permitted and constructed. Alternatively, the elements of the redevelopment can be incorporated with the final closure system. For example, it may be possible to utilize slabs, pavements, hardscaping and general grading fill as elements of the closure cap. Factors such as the procurement of predevelopment approvals, financing, and other real-estate transaction criteria may dictate that a conventional cover system be designed, permitted, and installed prior to construction of the post-closure redevelopment.
- *Integrity of Engineering Controls*: The post-closure redevelopment must be designed and constructed in a manner that is protective of the necessary engineering controls. Surface water management systems must comply with post-closure design criteria in addition to more restrictive criteria which may be dictated by land use ordinances or state regulations. Control of LFG is critical; the post-closure redevelopment will likely incorporate passive and active LFG systems. In addition, underslab venting systems will likely be required if the redevelopment includes buildings and other occupied (or potentially occupied) spaces. Depending upon applicable regulations, a clean soil cap may be adequate or a more extensive engineered geomembrane system may be required. In the event a geomembrane is necessary,

designs should incorporate appropriate connection and penetration details. In addition, design of the geomembrane system should consider to the stresses that may be imposed by post-closure settlement.

- *Geotechnical Considerations*: Without improvement, landfill materials are relatively loose, weak and unsuitable for support of structures. Landfill materials may contain voids and are subject to decomposition. The placement of grading fill will impose stresses on the landfill mass which will likely result in settlement and the possible presence of voids and/or pockets of very loose materials may result in differential settlements which would adversely impact the final cover system, other engineering controls and the post-closure redevelopment. Dynamic compaction (DC), i.e., impact densification by dropping a large weight on a regular pattern, is one technique used to densify the landfill materials, crush possible voids and loose zones and result in a mass that would have somewhat more predictable settlement characteristics. Even after DC is performed, post-construction settlement should be expected and measures to accommodate settlement should be incorporated in all designs.
- *Foundation Considerations*: Structures may be supported on foundations which transfer building loads through the landfill materials or on shallow foundations bearing on landfill materials which have been improved by DC. Each alternative involves specific risks and considerations. The use of pile foundations has been previously discussed (see Wind Energy). Even if structures are pile-supported, differential settlements relative to the adjacent grades are likely as the landfill materials settle under the weight of new fill. As a result, DC may be required outside of pile-supported building footprints to reduce the potential for sharp differential settlements. In addition, if the landfill is underlain by soft compressible natural soils, it may be necessary to supplement the DC program by implementing a surcharge program to pre-compress the natural soils. Even after the ground improvement program is implemented, designs should incorporate flexible couplings and utilities and other settlement-tolerant measures. It may be possible to support lightly loaded, settlement-tolerant framed structures on conventional spread footings after a comprehensive ground improvement program is implemented. However, designs based on the use of spread footing foundations should not be considered unless it is understood that the risk of settlement can be reduced but not eliminated.

Conclusion

After they have reached their design capacity, landfills often represent an under-utilized resource that can be redeveloped with a sustainable reuse. The selection of the most appropriate post-closure reuse will be controlled by a suite of diverse factors ranging from economics, local market demands, and available infrastructure. All landfill reuse designs should ensure that engineering controls are not adversely impacted while, at the same time, recognizing that landfill materials are not similar to competent natural soils and even if ground improvement measures are properly implemented, the risk of post-closure settlement is not eliminated.

Future Directions

Sustainable development is a unique and evolving concept. Sustainable landfill reuse is a new approach to the old planning technique of adaptive reuse. As sustainable landfill reuse projects are developed, new methods of measuring sustainability will be created. The sustainable development mantra requires current and future generations to use a systems approach to growth and development and to manage the natural, economic, and social aspects of projects. Landfill reuse will be one of the areas where this approach can be successfully implemented.

Glossary

Compacted clay liner (CCL) A barrier lining system used in landfills constructed primarily from compacted natural soil materials that are rich in clay, although the liner may contain processed materials such as bentonite.

Cover A multilayer barrier installed on top of the waste emplaced in a landfill, designed, planned, and constructed to control inflow of water, e.g., rain or snowmelt, into the waste to minimize the risk of disturbance by humans, animals, and plant roots, to control erosion, and to improve visual impact, i.e., human perception, of the facility.

Geocomposites A manufactured material used for drainage layers in landfills, which consists of a geonet sandwiched between one or two layers of nonwoven geotextiles.

Geomembranes or flexible membrane liners (FML) An essentially impermeable synthetic membrane used as barrier layers in landfills.

Geonets A net-like polymeric material formed from intersecting ribs joined at the junctions, which is used as drainage layers in landfills.

Geosynthetic clay liners (GCL) Subset of geosynthetics used as barrier layers in landfills consisting of rolls of fabricated thin layers of bentonite clay sandwiched between two geotextiles or bonded to a geomembrane.

Geosynthetics The generic term used for all of the synthetic materials used as barrier and drainage layers in landfills that include geomembranes, geosynthetic clay liners, geonets, geotextiles, and geocomposites.

Geotextiles Woven or nonwoven fabrics made from polymeric fibers generally used as a filter material for drainage layers in landfills.

Hazardous waste A waste with chemical and physical diversity, environmental persistence, and acute and chronic detrimental effects on human, plant, and animal health that is disposed of in landfills utilizing an extension of sanitary landfill technology using very conservative design criteria.

Leachate A potentially foul-smelling liquid, dirty water emanating from landfills, brownish, reddish, sometimes rust-colored acidic or basic water that may be loaded with a wide variety of contaminants, unless carefully and adequately controlled.

Lining A barrier between the void in which landfill waste is emplaced and the underlying soil on which the landfill is constructed. Designed and constructed to reduce any leachate outflow into the underlying soil or rock to an acceptable level.

Municipal solid waste (MSW) Garbage, trash, rubbish; waste collected from private citizens, households, possibly small businesses. Consists of food, food scraps, food leftovers, paper, plastics, textiles, cardboard, etc. Ideally, preferably, should not contain waste classified as hazardous. Ideally, preferably, should not contain recyclables, or not too many of them. Depending on local practices may or may not contain compostable organics, such as grass, plant, and tree cuttings. May contain batteries, paint thinner, nail polish, etc.

Mixed waste (MW) Contains both radioactive and chemically hazardous waste. In the USA, the radioactive waste component is regulated by the US NRC (Nuclear Regulatory Commission), the other hazardous waste by the US EPA (Environmental Protection Agency).

Natural attenuation The decrease in contamination that takes place over time naturally, i.e., without human intervention or interaction, as a result of reactions that take place naturally within landfills. Too slow, and too incomplete, to provide an adequate control method by itself, in most cases.

Nonvolatile dissolved organic carbon (NVDOC) Organic contaminants dissolved in the leachate.

Volatile organic compounds (VOC) Organic compounds that are likely to evaporate under typical landfill conditions, e.g., temperature and pressure. May include, e.g., gasoline, paint thinner, etc. Some are likely to be toxic or carcinogenic.

Definition of the Subject

Leachate refers to the liquid, contaminated water, that results from the interaction between any water in a landfill, e.g., as the result of rainwater infiltration, and the waste emplaced in the landfill. Leachate constitutes one of the major environmental and health risks associated with landfills. Typically, virtually always, leachate is a very complex liquid, with a wide variety of contaminants, many of which may be harmful to people and to the environment. As the waste and the landfill age, i.e., as reactions take place between the waste emplaced and any water within or percolating through a landfill, the composition changes, and hence the leachate composition changes. This further complicates controlling effluents emanating from landfills. Leachate control, i.e., preventing unacceptable damage to people and to the environment is a critical aspect of the design, planning, construction, operation, and closure of landfills. It also is a major challenge for landfill operators, owners, users, and regulators.

Because leachate contamination results from the interaction between waste and water, one line of control is to manage the types of wastes emplaced. A second line of control is to control water inflow and outflow. A third control approach is to operate the landfill in a mode that minimizes the formation of potentially damaging products, and optimizes the probability of enhancing reactions and interactions that reduce the detrimental aspects of leachate composition. Given the complexity of the problem, e.g., the

variety of waste products that may be emplaced, and the variety of operating conditions (e.g., in terms of water content, water flow, temperature), it is not surprising that landfills continue to pose serious challenges, and that leachate control is a difficult target to reach.

Waste input management is accomplished in part by specifying what type of waste can be accepted by landfill operators. In the USA, e.g., a clear distinction is made between landfills that are permitted to accept hazardous waste and landfills that can accept municipal solid waste only. Although conceptually and in principle this might be considered to be a simple and straightforward distinction, in practice it remains fraught with uncertainties. As a most obvious example, it will be understood that it is relatively easy for some types of potentially hazardous materials to become intermixed with municipal waste, whether intentionally or unintentionally, and it is essentially impossible for the operator to check the waste emplaced in a landfill in full detail.

A sea shift of massive proportions with an enormous impact occurred in the 1970s, when the extensive environmental impacts of the up to that time exceedingly casual approach to waste disposal finally became recognized. As a result of the extensive regulations introduced since that time, landfill design, planning, operations, and closure have become an exceedingly sophisticated endeavor, aimed at protecting the public and the environment from the potentially harmful effects of uncontrolled landfill operations, and in particular of uncontrolled leachate formation and releases. In parallel with the regulatory and operational improvement in practices has been the development of major research efforts, aimed at improving the understanding of what actually happens in landfills, and of how the control of leachate in particular can be improved. This ongoing and continuing research has resulted in a vast literature dealing with virtually every conceivable aspect of leachate control.

While it is true that in most advanced societies rigorous rules and regulations have been emplaced in order to control landfill leachate, it is equally true that this frequently is not the case in many less-developed societies, where landfill leachate control frequently is not yet perceived as a high priority. Hence environmental and potential health impacts of landfill operations in many parts of the world can be considered as being more of the open dump–type operations common in most of the world until about 50–70 years ago, i.e., casual dumping in holes in the ground, or even on the surface, with minimal attention paid to any potential health or environmental hazards associated with the waste emplacement.

Introduction

Controlling leachate is an essential yet difficult-to-achieve objective of landfill design, construction, operations, control, and regulations. In relatively wet climates leachate is unavoidably associated with landfills. In arid climates, the amount of leachate may be minor, inconsequential, and of little concern. In semi-arid climates, leachate may develop on an intermittent basis, e.g., seasonably, following periods of intense rainfall or snowmelt.

The composition of the leachate, which largely results from the interactions between water and the waste emplaced in the landfill, will be affected significantly by the waste with which the water comes in contact and with which it interacts. "Leachate may be composed of liquids that originate from a number of sources, including precipitation, groundwater, consolidation, initial moisture storage, and reactions associated with decomposition of waste materials. The chemical quality of leachate varies as a function of a number of factors, including the quantity produced, the original nature of the buried waste materials, and the various chemical and biochemical reactions that may occur as the waste materials decompose [1, 2]." Hence a primary consideration in determining leachate composition will be the determination of the waste inventory and its characteristics. This will notably include the physical, chemical, and biological composition of the waste.

Methods used to maintain an adequate control over the leachate include first and foremost landfill design, construction, and operations. Site selection will be a first major step in providing assurance that leachate discharges can be controlled, and that their impact on the environment, e.g., on groundwater and on surface waters will remain within acceptable limits. Landfill designers will pay particular attention to liners and covers (Fig. 1). These will control the influx into the

Landfill Leachate Control. Figure 1
(**a**) Waste emplaced in landfill with bottom liner and cover (Modified from Ref. [16], Fig. 6-2, p. 326); (**b**) waste emplaced in landfill installed directly on in situ ground, protected by cover (Modified from Ref. [16], Fig. 6-1, p. 325)

landfill and the outflow from the landfill. Because waste composition is such an important aspect of leachate characteristics, the extent to which waste composition can be controlled will certainly be a significant factor in leachate development, and would be one of the prime modes of control. Waste input control frequently poses difficult challenges.

Liners may be constructed of compacted soil, of soil amended with additives, e.g., clay, to reduce the permeability of the liner, or with geosynthetics such as geomembranes and geosynthetic clay liners. A number of standard, recommended, and widely used designs are available. Design differences are explainable in part based on the performance requirements of a particular liner for a particular application. These performance requirements in turn will depend on a number of variables, notably on the leachate characteristics, on the climate (especially rainfall and temperature ranges), on the topography of the location of the landfill, and on the proximity to the groundwater table and to any surface waters.

Covers control influx into the landfill. Cover design will depend to some extent on the climatic conditions at the site, with somewhat different approaches possible in arid or semi-arid climates as compared to wet ones. The usual classical approach to cover design will emphasize the objective of minimizing water inflow into the landfill. A significant aspect of cover design and construction will be the control of runoff and of infiltration.

Leachate monitoring is a desirable integral part of landfill operations. This includes volumetric control (flow) and quality control (chemical composition, sediment load, etc.). Leachate treatment is extremely helpful in reducing potential harmful impacts of landfill operations.

While it is likely that over time, for many situations, leachate control requirements will decrease as interactions between waste and water slow down, and effluent quality improves, it nevertheless must be assured that post-closure controls, preferably passive only, if at all possible, should be sufficient to assure that no unacceptable detrimental environmental impacts will develop.

The European Council Directive on Landfill classifies landfills into three categories: landfills for hazardous waste, landfills for nonhazardous waste, and landfills for inert waste [3]. Very similarly, roughly parallel, is the US Environmental Protection Agency's classification of landfills into industrial waste landfills, construction and demolition debris landfills, and municipal solid waste landfills (e.g., [4]). The Environmental Protection Authority of New South Wales, Australia, classifies waste in six classes: special waste (clinical and related, asbestos, tires), liquid waste, hazardous waste, restricted solid waste, and putrescible or nonputrescible solid waste [5]. Clearly, whatever classification might be used, broad categories of waste types exist and are recognized. Equally obvious, the leachate resulting from emplacing various waste types in landfills will be very different and will have very different

health and environmental impact implications. As a result, it is clear that correspondingly different regulatory requirements will be imposed on all aspects of landfill planning, design, operation, and closure, and notably on leachate treatment and management.

A critical initial step for leachate control in new landfills is site selection. Geology, hydrology, hydrogeology, geomorphology, and geochemistry are among the topics to be considered when selecting a site for consideration for the location of a future landfill. In principle it would be desirable to consider climate as well, but presumably in general climate variations among potential nearby sites will be fairly minor, unless options are available such as leeside of hills and mountains and consequent significant differences in rainfall, snowfall, wind, and temperature that might provide a basis for preferential location, assuming that the local microclimates are known sufficiently well.

Knowledge of the regional and local geology will be exceedingly helpful in identifying sites that would be attractive for landfill location vs. sites that would be singularly unattractive. It certainly is preferable to consider sites with simple, well-understood geology as compared to sites with complex, especially grossly disturbed geology. Of particular interest will be the hydrology and hydrogeology of the site, in a broad sense: What are surface and underground water flow patterns? Is the surface topography such that any rainfall or snowmelts is likely to result in inflow into a potential landfill? Will extensive, hence expensive, engineering measures be required to minimize such inflows (e.g., diversion ditches, trenches, or berms)? If so, will there be a post closure maintenance requirement for such engineered structures?

Groundwater flow most commonly will be the dominant concern for landfill site selection. At what depth is the water table? What is the flow pattern at the site? What is the flow rate? Head (water pressure)? Will major engineered structures be required to reduce water inflow to an acceptable level (e.g., impermeable barriers installed in trenches upstream of the landfill, grout curtains, formed by injecting grout into the upstream geological formations in order to reduce water inflow into the landfill to an acceptable level)? While such approaches are technologically feasible, they are expensive, and they raise questions with regard to durability, longevity: will they require long-term inspection, monitoring, and maintenance? If so, how extensive, intensive? Who will have the responsibility for these activities?

The first step in a geological/geotechnical site characterization will consist of collecting, collating, and analyzing all available information about the site being considered. This will start from the regional geology, which, in many parts of the world is known sufficiently well to allow an initial assessment as to whether or not a particular location appears promising from a general geological and geotechnical point of view. The next step in what virtually always will be an iterative approach to site characterization may consist of initial onsite geological mapping, and study of aerial photography and remote sensing data that are available. If, on the basis of this initial office and preliminary field work, it is concluded that further investigation is warranted, the site investigation will proceed to a first phase of intense field work.

Detailed geological mapping is likely to be the first step in a comprehensive site characterization, followed by detailed geophysical surveys. A variety of geophysical methods can be used, in order to improve the understanding of the lithological formation configuration at the site and, in particular, to gain an improved understanding of the distribution of geological formations that will facilitate water flows (aquifers) and formations that will impede water flow (aquitards). Geophysical surveys will provide initial information about soil and rock properties important for water flow such as density, porosity, and water table depth. They will provide information about the continuity and uniformity of the host formation, about the depth to bedrock, and bedrock topography, and about major geological disturbances that might affect the containment functionality of the site.

Once a comprehensive understanding of the site geology has been obtained, it is desirable to determine physical characteristics of the host formations. Superficially, this can be accomplished with trenching or the excavation of test sample pits. Sampling to greater depth most likely will require drilling, or, if dealing with relatively weak and soft soils, by driving sampling tubes into the ground. Around this time it also would be desirable to start collecting initial groundwater samples in order to establish a base line of the groundwater composition prior to any landfill construction

disturbance. Similarly, at this time it would be highly desirable to install monitoring wells, as these will allow the determination of a much more precise and reliable understanding of local groundwater flow patterns and rates. It is highly probable that any such wells initially will be used to conduct hydrological site characterization testing including, e.g., pumping and injection tests. Such tests will provide large-scale information about the main parameters that will influence subsurface water flow such as hydraulic conductivity, aquifer transmissivity, piezometric head, and hydraulic gradient. Knowledge of these parameters, combined with the understanding of the geology of the site, will make it possible to numerically model subsurface flow paths, patterns, and intensity, e.g., volumetric flow rates. Such models will assist in estimating what the potential consequences might be of leachate breaching the containment liners.

At sites where the water table is well below the planned bottom of the proposed landfill, it would be highly desirable to also characterize the vadose zone, i.e., the ground in between the landfill bottom and the water table, where the pore space is not fully filled with water. In these situations, it is this unsaturated zone that would be the first recipient of any leaking leachate. Therefore it is highly desirable to understand what the consequences might be of any leakage into this zone. Fluid flow, and even more contaminant flow, and dispersion in soil or rock where pores are filled with water only partially remains a difficult topic, probably at the edge of the current state of the art, and most certainly in need of more research and development.

The geological host formations on which an eventual landfill will be constructed can form a major last line of defense against any contamination by leachate, e.g., in a situation where all engineered components (liners and covers) have failed. Hence, it is highly desirable, if not always possible, to select sites where the host formations can be as effective as possible as natural barriers.

Landfill Liners

A major concern about landfill leachate is that it might affect groundwater and soil, and on some occasions, surface waters. The first line of defense against leachate contamination of groundwater is by installing liners prior to waste emplacement, in order to form a barrier and minimize the risk that leachate might escape the landfill and contaminate nearby soil, ground water, or surface water.

A wide variety of liners, liner systems and liner designs are available. A lining system consists of barrier and drainage layers where compacted clay liners (CCL) or geosynthetics such as geomembranes, geosynthetic clay liners (GCL), and/or a combination of these may be used as barriers for the containment of liquids, sludges, and leachate generating solids. Compacted clay liners are constructed primarily from compacted natural soil materials that are rich in clay, although the liners may contain processed materials such as bentonite. Compacted clay liners are compacted in lifts of 150 mm up to total liner thicknesses generally ranging from 0.6 to 0.9 m up to as much as 3 m. US EPA requires that compacted clay liners have a hydraulic conductivity equal to or less than 1×10^{-9} m/s (e.g., [6–8]). Geomembranes or flexible membrane liners (FML) are essentially impermeable, relatively thin sheets of polymeric materials composed of semi-crystalline thermoplastics such as high-density polyethylene (HDPE), linear low-density polyethylene (LLDPE), very-low-density polyethylene (VLDPE), and flexible polypropylene (FPP); thermoplastics such as polyvinyl chloride (PVC); and thermoplastic elastomers such as chlorosulfonated polyethylene (CSPE). The thickness of geomembranes ranges from 0.75 to 3 mm (30–120 mil) [9]. A geosynthetic clay liner (GCL) is a relatively thin layer of processed clay (typically bentonite) either bonded to a geomembrane or fixed between two sheets of geotextile where a geotextile is a woven or nonwoven polymeric fiber that is less impervious to liquid than a geomembrane, but more resistant to penetration damage. In GCL configurations using a geomembrane, the clay is affixed using an adhesive whereas in GCL configurations consisting of geotextiles, adhesives, stitchbonding, needlepunching, or a combination of the three are used. The main advantages of GCLs are the allocation of more landfill airspace for waste disposal since GCLs are not as thick as a liner system involving the use of compacted clay [10] and the relatively low hydraulic conductivities of most sodium bentonite GCLs that lie in the range of 1×10^{-11} to 5×10^{-11} m/s [9]. Granular material or geosynthetics such as geonets, geotextiles,

and geocomposites may be used for the landfill drainage layers. Granular materials used for drainage layers are sand and gravel where sand is generally used as a filter material and gravel is used as the drainage material. Geonets are net-like polymeric materials formed from intersecting ribs joined at the junctions that meet in-plane flow rate regulations. Geocomposites consist of a geonet sandwiched between one or two layers of nonwoven geotextiles (e.g., [6–9]).

The primary objective of these lining systems is waste containment in the form of low permeability soil ponds, surface impoundments, municipal solid waste, and hazardous waste landfills. Disciplines such as geotechnical engineering and polymer science are utilized in the design of these lining systems. Various types of lining systems with six variations are illustrated by Fig. 2. These six variations fall into two main groups: single liners and double liners. A double lining system is created with the addition of a second liner. It consists of two liners and an intermediate drainage layer. This intermediate drainage layer is depicted as a granular soil but in fact can be comprised of a variety of drainage media, including geosynthetic materials such as geonets or geocomposites in addition to granular soils. The primary feature of the double liner (Fig. 2d–f) is the intermediate leakage detection and removal layer or the secondary leachate collection system, which allows the detection of any leakage through the top liner before that leakage has exited the overall lining system. With a single liner (Fig. 2a–c), leakage detection is only possible outside of the lining system, in which case the containment objective has been violated (e.g., [11, 12]).

Any of the six lining configurations shown in Fig. 2 may also contain leachate collection systems or primary leachate collection systems above the topmost (primary) liners. The leachate collection systems may be either comprised of granular soils, i.e., a sand drainage and protective layer; or geosynthetic materials, i.e., a geotextile filter layer sandwiched between an underlying geonet drainage layer and an overlying sand protective layer. The leachate collection system removes leachate to a sump through some form of collection system in order to reduce the leachate head.

The single liner has all but disappeared as a viable option for the containment of liquids and wastes in the USA, not because of any particular shortcoming on the part of clay-only or geomembrane-only liners, but

Landfill Leachate Control. Figure 2

Types of lining systems: (**a**) single compacted clay liner; (**b**) single geomembrane liner; (**c**) single composite liner; (**d**) double geomembrane liner; (**e**) double liner with geomembrane top liner and composite bottom liner; and (**f**) double composite liner with composite top and bottom liners (Modified from Ref. [11], Fig. 1, p. 138)

because it has been clearly demonstrated through considerable research, primarily in the USA (e.g., by [13–15]) and as quoted by [9] that a composite liner composed of both geomembrane and compacted clay performs in a superior manner to either alone. Double composite liners with both primary and secondary leachate collection systems have been widely adopted in solid waste landfills in the USA.

Figure 3 presents a section through a typical double-lined landfill composed of a geomembrane top

Landfill Leachate Control. Figure 3
Section of a double lined landfill profile (From Ref. [1], Fig. 1, p. 7)

liner and composite bottom liner. The profile is made up of three subprofiles containing a total of 11 layers. Immediately above the bottom (secondary) geomembrane/clay composite liner is the secondary (bottom) leakage detection and drainage layer to collect leakage from the primary geomembrane liner. Above the primary liner is the primary (top) leachate collection layer that is composed of a geosynthetic drainage net (geonet) and a sand layer that serve as drainage layers for leachate collection. The sand drain layers are typically at least 0.305 m (1 ft) thick and have suitably spaced, perforated or open joint drain pipes embedded below the surface of the liner. The leachate collection drainage layer serves to collect any leachate that may percolate through the waste layers in an attempt to avoid significant buildup of the leachate head and to limit the leakage. The liners are sloped to prevent ponding by encouraging leachate to flow toward the drains. The primary goal is to minimize the volume of the leachate that might percolate through the primary (top) liner and to virtually prevent any migration of leachate through the secondary (bottom) composite liner that would eventually be directed to the natural formations below and might lead to violating the containment objective. The first subprofile (topmost part) of the landfill consists of a cap or cover system. At the base of the cap is a drainage layer underneath which a composite liner system is installed similar to the secondary (bottom) lining system used at the base of the landfill. The top of the barrier soil layer is graded so that water percolating into the lateral drainage layer will be diverted toward some kind of removal system (drain or sump). A layer of soil suitable for vegetative growth is placed above the lateral drainage layer to complete the cap system [1, 2].

The US Environmental Protection Agency (US EPA) requires composite lining systems (both clay and geosynthetic) with leachate collection for municipal solid waste landfills (RCRA Subtitle D, 40 CFR §258.40(a) [2]) or equivalent performance (40 CFR §258.40(a) [1]), and double composite liners with leachate collection and detection systems for all hazardous waste landfills (RCRA Subtitle C, 40 CFR § 264.301). Some individual states in the USA require double composite liner systems for municipal solid waste landfills as well (e.g., 6NYCRR Part 360 and Michigan NREPA Part 115 as referenced by [9]). A typical double composite lining system (Fig. 2f) from bottom to top consists of a 0.6 m thick compacted secondary (bottom) clay liner (or an alternative liner that can be equivalent to a 0.6 m thick compacted clay liner), followed by a secondary (bottom) geomembrane liner, secondary (bottom) leachate collection (or leak detection) layer, a minimum 0.6 m thick primary (top) compacted clay liner (or geosynthetic clay liner that can be equivalent to a 0.6 m compacted clay liner), a primary (top) geomembrane liner, and a primary (top) leachate collection system. This succession is overlain by a 0.6 m thick protective sand blanket. The leachate collection system consists of a layer of synthetic geonet and geotextile. The former provides good in-plane drainage conveyance and the latter good cross-plane drainage together with the ability to exclude (filter out) fines. The geomembrane must be at least 1.5 mm (60 mil) thick if made from high-density polyethylene (HDPE), or 0.75 mm (30 mil) thick if made from other resins. The permeability of the subbase and of the compacted clay liner must not exceed 1.0×10^{-9} m/s [9].

Landfill Covers

A major reason for the development of landfill leachate is the interaction between water and emplaced waste. A first line of defense against such interactions is the installation of covers that will minimize the inflow of water into the emplaced waste. A variety of cover methods are available, and a variety of cover design approaches. Cover design will depend significantly on the local climate, and will be different for landfills in wet, dry (arid), or intermediate (semi-arid) environments.

Operational covers, typically emplaced daily, and final closing covers installed at the end of the life of the landfill are distinguished. Daily soil covers are placed in relatively thin lifts and compacted daily to hide the wastes in an attempt to limit the access of nuisance insects and to prevent as much as possible spreading of any potential disease from the landfill.

Figure 4 presents an alternative landfill final cap/cover system composed of seven typical layers, namely, a vegetation/soil top layer, biotic barrier layer, filter layer, drainage layer, barrier layer, gas collection/venting layer, and foundation layer. The vegetation/soil

Landfill Leachate Control. Figure 4
Alternative landfill final cover/cap system (Modified from Ref. [16], Fig. 6-6, p. 334)

top or erosion layer consists of fertile topsoil suitable for vegetation growth to minimize erosion and to promote evapotranspiration. The main purpose of the vegetation/soil top layer is to store infiltrated water until it is later removed by evapotranspiration. The biotic barrier layer placed below the vegetation/soil top layer consists of cobbles to form a barrier against plant roots and burrowing animals. A filter layer composed of geotextiles may be placed between the biotic barrier layer and drainage layer to minimize clogging of the drainage layer by soil particles. The drainage layer placed below the protective layer mainly serves to reduce the water head acting on the barrier liner to reduce infiltration and most importantly, to reduce pore pressures in the cover soil to improve slope stability of the final cover. Granular material such as sand or gravel or geosynthetics such as geonets and geocomposites are generally utilized for the drainage layer. It should be noted that a drainage layer may not be needed for a final cover system located in an arid region. The barrier layer, generally consisting of a geomembrane/compacted clay composite liner or a geosynthetic clay liner (GCL), as an alternative to the compacted clay liner, minimizes percolation of water from the overlying cover system and prevents landfill gases from escaping into the atmosphere and causing air pollution. The gas collection/venting layer constructed of granular material (i.e., sand, gravel) or geosynthetics (i.e., geonet, geocomposite, geotextile) serves to collect gasses originating from the decomposition of the waste or volatile organics released from the waste. The foundation layer is generally the interim soil cover that has been placed on the waste and possibly subjected to some additional compaction which supports the final landfill cover. The gas collection layer and the foundation layer may be combined to form a single layer if the gas collection layer is made up of sand [7, 16]. Chapter entitled "► Landfill Closure and Reuse of Land" provides additional information on landfill final covers.

Landfill Runoff/Infiltration Control

A primary method of minimizing the formation of leachate is to minimize water inflow into a landfill. A major method for achieving this objective is to install covers that will minimize infiltration, and that will in part divert some precipitation in the form of runoff. Runoff is promoted but controlled to prevent excessive erosion of the landfill cap. Section "Landfill Covers" above and chapter "► Landfill Closure and Reuse of Land" provide information on infiltration control through landfill final covers.

A good procedure for promoting surface runoff and for controlling erosion is to maintain cap/cover slopes at 2–5% and to increase the slope gradually toward the sides of the cover (e.g., as can be observed in Fig. 1). For long, uniform slopes steeper than 5%, runoff diversion in the form of benches excavated at right angles to the slope which intercept the sheet flow may need to be constructed to control erosion along the cover system. The accumulated flow along the benches may be directed toward down chutes which convey the flow to lower benches or away from the cover. The spacing of the benches and down chutes should be based on climate and local factors and should not be established arbitrarily [7].

Landfill Leachate Monitoring

The formation of leachate depends on numerous complex interactions between the waste in the landfill and the water that penetrates into the landfill. Types of wastes emplaced vary considerably among different types of landfills. As the resulting leachate will depend heavily on the waste types emplaced, and on the waste–water interactions, considerable differences exist among leachates from different landfills. Moreover, the composition of the leachate varies over time, as the reactions change, e.g., in response to the changing composition of the materials in the landfill. In order to obtain a good understanding of leachate development, it is highly desirable to monitor leachate development and flow. This includes monitoring volume, flow rates, and, in particular, composition.

It seems highly likely, virtually certain, that leachate monitoring will become a standard operating practice for most if not all large landfills in the future. Monitoring will give the operator, the regulator, and the public greatly increased confidence that no detrimental consequences are resulting from the landfill operation.

Given that one major concern, usually the ultimate concern, associated with landfill leachate is the risk that it might contaminate groundwater, it is likely that in many situations the highest monitoring priority will be the establishment of a system that provides early warning in the eventuality of a release from the landfill.

The European Communities have established minimum requirements for landfill monitoring ([3], Annex III). These include monitoring of meteorological data, emission data, groundwater monitoring, and monitoring of the landfill topography, i.e., settlement monitoring. Meteorological monitoring is aimed at providing input data for water balance studies, which in turn will help to identify whether or not leakage might be occurring. Weather data to be recorded include precipitation, temperature, wind strength and direction, evaporation, and atmospheric humidity. During the operational phase, these data are to be recorded daily, but the measurement frequency is reduced greatly (mostly to monthly) during the aftercare phase. Leachate and surface water, if any, is to be sampled at representative points. Leachate measuring and sampling is to be performed at all points at which leachate discharges from the site, and will include measurements of volume and of composition. The sampling frequency can be adapted, based on the morphology of the waste, but needs to be specified in the permit. Typically, volumes will be measured monthly, compositions quarterly during the operational phase, every 6 months thereafter. Groundwater protection monitoring is aimed at detecting any early releases that might compromise the integrity of the groundwater. As a minimum, this requires a monitoring point in the inflow region, and two monitoring points in the outflow regions. However, the number of monitoring points can be increased on the basis of local hydrogeology. For landfills to be permitted in the future, base reference-level values must be established prior to commencing waste emplacement. Leachate sample analyses to be performed will be determined based on the expected waste composition and on the quality of the groundwater in the area. Of particular importance is the early recognition of indicator parameters that might provide an early warning of potential problems – indicators such as pH, TOC (Total Organic

Carbon), phenols, heavy metals, oil, and/or hydrocarbons. On the average, for typical situations, groundwater level is to be determined every 6 months, although this frequency is to be increased at sites with significant water level fluctuations. Composition determination of samples is to be performed at a frequency depending on the groundwater flow rate, and in particular on the feasibility of taking responsive remedial action before the next sampling. Trigger levels should be established, based on the local groundwater quality, and taking into account the local hydrogeology. If at all possible the trigger levels should be included in the permit for the site, and should form the basis for reporting to the regulatory authority when reached.

The monitoring program developed by the US Environmental Protection Agency essentially parallels the European community approach [17]. A section through a typical monitoring well installation is shown in Fig. 5. Figure 6 presents an example of an installation to monitor an interbedded aquifer (in this example, a low permeability clay bed in between two much more permeable sand layers): a PVC pipe installed coaxially in a borehole allows withdrawing water samples from the screened section of the hole. Above the screened section the pipe is carefully sealed, in this example with bentonite and cement/bentonite grout, in order to assure that no fluid can flow in the annulus in between the PVC pipe and the well walls. Surface structures protect the installation against vandalism or accidental damage. A critical and very important aspect of monitoring well installation is to minimize, as much as possible, any disturbance and especially contamination of the conditions that one intends to observe with the well.

Major components of monitoring projects include groundwater monitoring, leachate monitoring, monitoring of gas generation, of subsidence, surface erosion, and air quality. This approach stresses that both the quantity and quality of the leachate that develops are good indicators of how successful the operation is controlled.

A serious limitation of many landfill leachate effluent monitoring programs is the heavy reliance on well monitoring. By definition, wells monitor at points. Depending on the local geology and geohydrology, this may or may not be satisfactory. Certain is that in many natural environments fluid flows, and contamination plumes in particular, may pursue highly

Landfill Leachate Control. Figure 5

Monitoring well arrangement: monitoring wells upstream (*left*) and downstream (*right*) from landfill, with provisions for sampling in aquifers (sand) and aquitard (clay) (From Ref. [17], Fig. 12-1, p. 142). k = hydraulic conductivity; W.T. = water table

Landfill Leachate Control. Figure 6
Monitoring interbedded aquifer. The monitoring well is installed downstream from the landfill, and allows sampling of groundwater from the screened interval. If excessive concentrations of contaminants are detected in these samples, it indicates that excessive leachate leaking has taken place, and remedial action may be required (From Ref. [17], Fig. 12-2, p. 142)

preferential paths that can readily bypass measurements at a few points only. One possibility to address the uncertainties resulting from monitoring in wells is to complement such measurements with geophysical surveys. Geophysical surveys, by definition, can provide information about large volumes of ground. Geophysical surveys depend on differences in physical properties in the ground surveyed in order to detect

anomalies. If a correlation can be established between some physical property, e.g., electrical resistance, or electrical conductivity, and a contamination plume, it may be possible to gain a much more comprehensive assessment of site conditions, e.g., downstream from a leaking landfill, using geophysical surveys.

Landfill Leachate Treatment

In response to the numerous types of leachate that have developed in landfills, a wide range of leachate treatment methods have been developed, and are being implemented, tried out, and researched, with the objective of identifying methods most appropriate for particular waste types, water inflow and outflow rates, and waste–water interactions. The objective of treatment is to reduce the contaminant load in any effluent to an environmentally acceptable level, at an acceptable cost.

Under unusually successful treatment, it may be possible to discharge the now clean "leachate" directly into surface or underground waters. Under some situations it still may be possible to rely on natural attenuation as the major or exclusive treatment option. However, relying on natural attenuation only is likely to become less and less acceptable, except under the most unusual circumstances where it can be demonstrated convincingly to be adequate. Much more likely today is that leachate will require further treatment. One option is to convey leachate to sewage treatment facilities, and to treat leachate co-jointly with sewage. This certainly will require that the sewage treatment facility has adequate capacity, and allows for treatment that will clean the leachate without interfering with regular sewage treatment operations. This will require careful collaboration with the sewage treatment operations in order to assure mutually beneficial, preferably optimal co-joint treatment.

Major leachate treatment methods include recirculation, physical, chemical, and biological treatments. Recirculation should result in enhancing and accelerating all reactions taking place within the landfill, and hence should promote reaching earlier a waste and leachate composition less likely to result in excessive environmental impacts. Under what would usually be considered the very best practices for municipal waste landfills today, the landfill effectively is operated as a bioreactor, with controls in principle, in concept, very similar to those for chemical reactor vessels in general. Obviously, given the complexity of the system, and the numerous associated uncertainties, e.g., with regard to emplaced waste, and possibly inflow and outflow uncertainties, enhanced by the fact that the "reactor" operates in a natural environment, with far from complete control over the environment, e.g., with respect to temperature, pressure, humidity, designing, planning, and operating such a reactor remains a challenging task. Comprehensive information on landfill bioreactor design and operations is given by [18] and in chapter "► Landfill Bioreactors."

The use of constructed wetlands to treat landfill leachate appears to be gaining favor [19] as one more treatment option that has highly desirable benefits under the appropriate conditions. Considerable experience has been gained about the use of wetlands for the treatment of a variety of wastewaters, notably including acid mine drainage, urban storm water runoff, agricultural wastewaters, and sewage. Obviously one very attractive feature of constructing wetlands is that it assists in rebuilding some of the wetlands that have been lost over the last decades, or centuries. Equally obvious, treatment wetlands must remain environmentally acceptable.

Two major types of constructed wetlands for wastewater treatment are surface flow and subsurface flow systems. As the name implies, surface flow systems rely on water flow in an open system, open to the atmosphere. In a subsurface system, the main flow is below the surface (Fig. 7).

As with all leachate treatment systems the performance will depend on multiple factors with complex interactions, but one basic critical variable will be water flow rate and water replacement. Similarly to landfills themselves, a first step in estimating these variables will be the determination of the water balance:

$$\frac{dV}{dt} = Q_i - Q_o + P - ET$$

where V is the water volume, t is time, Q_i is the leachate inflow rate assuming no other inflows exist (V/t), Q_o is the outflow rate (V/t), P is the precipitation rate (V/t), and ET is the evaporation rate (V/t).

Obvious from this simple equation is that a number of climatological variables will affect the flow rate, possibly the water volume or water level, and hence the treatment effectiveness of a constructed wetland.

Landfill Leachate Control. Figure 7
Representative section through a subsurface flow system constructed wetlands for the treatment of wastewater (From Ref. [20], Fig. 3-1, p. 16). Leachate flow is guided through a highly permeable layer, e.g., gravel, coarse sand, installed directly above an impermeable base barrier, and covered by a soil that will permit and encourage plant growth

Rainfall intensity and pattern will influence performance, as will evaporation, and hence wind, temperature, and humidity. Strongly preferable is to collect such data on a local and a representative level as possible, although, in particular, for preliminary planning purposes it may be necessary to rely on regional data. As for landfills themselves, site selection, in particular with regard to subsurface hydrology, but also with regard to potential surface water flow, especially flooding, as well as foundation barrier performance, will be given high priority as a first and major line of defense against unacceptable environmental impacts.

The cleansing effects that take place in the wetlands treatment facility are similar to those in other leachate treatments. Physical activities will include the settling out of some solids, precipitation, the filtering out of others, and the adsorption of others on various surfaces within the wetlands. Chemical precipitation and adsorption will remove nitrogen and phosphorous. Chemical decomposition will remove or at least greatly reduce bacterial and viral content. Biological reactions will contribute to the removal of various organics, and may assist in the uptake by plants of heavy metals, at least temporarily. The latter aspect raises a question that needs to be researched more: is there a risk of treatment wetlands becoming cumulatively loaded, over time, with excess contaminants? Could there come a point where further decontamination of treatment wetlands themselves becomes a requirement?

Notwithstanding some remaining uncertainties, it is clear that constructed wetlands for leachate treatment provide multiple benefits that may make them highly attractive. These include typically low operating and maintenance costs, wildlife benefits, and visual attractiveness benefits. An issue that may be of concern, depending on the local climate, and the proximity to human habitat, is the risk of mosquito development.

Landfill Leachate Disposal

Depending upon the treatment that leachate has undergone, a range of options may be available for disposal of the residual wastes left over after leachate treatment. Depending upon the type of treatment to which the leachate has been subjected, the residual waste is likely to be significantly different, and may require different disposal methods, options, and approaches. Disposal requirements are reduced greatly by the ever more common practices of leachate recycling and neutralization.

Landfill Post-closure Control

Landfill post-closure control will be a strong function of potential risks associated with post-closure landfill performance. Of particular concern will be the risk of gas formation, gas collection, gas emissions, and associated health and safety risks. Of prime importance will be any anticipated continued methane gas development. If this is anticipated, gas control measures will be required.

Leachate control will be required to prevent detrimental impacts from leachate escapes. Liners and covers are the primary means of defense against problems caused by leachate formation and outflow. In many situations, it will be desirable to provide active leachate control as well, at least for some time. Active control can be achieved, e.g., by collecting all leachate in low points in the landfills, "sumps," and either allow drainage and collection by gravity flow from such collection points or implement pumping from such points.

To what extent the surface area and the buffer zone surrounding landfills can be redeveloped, put to alternate use, and to what kind of use, will depend on the location as well as on the characteristics of the emplaced waste and of the anticipated future development of leachate, gas, waste, potential releases – what are health, safety, and environmental risks associated with the site post-closure? Whereas in the past, closed landfills, sometimes with minimal, if any, controls, have been used for a variety of purposes, including housing, residential and commercial developments, parks and recreational areas, etc., it is certain that in the future, society will insist on a much more careful approach to such practices, in part at least, because of serious disasters that have resulted from past approaches of this type.

For some hazardous waste landfill sites it seems rather obvious that the operator or some subsequent responsible party will have to maintain and assure physical control over closed landfill sites. On the other hand, for landfills loaded with only relatively innocuous material, it may continue to be possible, given adequate site characterization, possibly complemented by monitoring, that the site might be restored to public use.

Municipal waste landfills, in particular, for obvious reasons, are frequently located relatively close to urban areas. In fact, not uncommonly one of the main challenges for landfill operators is to maintain acceptable relations with an ever closer and more intense encroachment from developments. Conversely, if it were possible to convert the landfill area, upon closure, to an acceptable public use, it obviously would benefit all parties involved.

Landfill leachate monitoring is an integral part of modern landfill operations, including post-closure monitoring. The location of monitoring wells will be determined based on local groundwater flow patterns (Fig. 8). The frequency of sampling and testing will be based on test results (Fig. 9). If test results indicate that unacceptable releases are taking place (Fig. 10), remedial action may be required.

Future Directions

The last few decades have seen major recognition of the potentially serious problems associated with landfill disposal of various wastes. Considerable efforts are being focused on reducing waste generation, on recycling, on composting, on waste incineration, on waste combustion with energy generation, and in general on waste management strategies aimed at reducing and minimizing the need for landfill emplacement. Even so, it appears highly likely that for the foreseeable future landfills will continue to form a major component in waste management and disposal strategies.

Understanding of leachates generated at landfills has improved significantly over the last few decades. This improved understanding in turn has resulted in greatly improved leachate control strategies. Even so, serious doubts and uncertainties remain associated with leachate control, particularly with regard to long-term performance. Hence it is essential that research be continued in this area and, in particular, that an improved understanding about leachate generation and control under actual field conditions over extended periods of time, at least decades, is gained. This unquestionably will assist in the development of further improvements in leachate control strategies and approaches.

Given the vast range of actual implementation options that are being pursued in many parts of the world, under many widely ranging conditions, i.e., waste types and contents, climatological environments, control and operational measures implemented, etc., it is clear that over the next several decades an exceedingly large data base of practical results will be obtained. Most modern landfills are monitored, instrumented, and tested, some extensively. All of this monitoring and testing provides extremely valuable data to calibrate theoretical models that continue being developed. Hence it is certain that models, and input data for the models, will continue to improve. Experience is being gained over decades, eventually many decades. This will provide currently sorely

Landfill Leachate Control. Figure 8
Example of possible groundwater flow paths near and through a municipal solid waste landfill (MSWLF). Monitoring wells will be installed downstream, to allow sampling of effluent downstream from the fill, in order to assess whether leachate releases, if any, remain within allowable limits (From Ref. [16], Fig. 5-2, p. 238)

lacking information about long-term in situ leachate development which in turn will provide feedback to improve and optimize future control strategies.

It seems virtually certain that in developed societies landfill operations will continue to shift toward a bioreactor operational mode, i.e., systems in which leachate generation will ever more tightly be controlled through the monitoring and manipulation of operating variables. As a result, it seems highly probable that it will be possible to continue to reduce potential health and environmental impacts of landfills.

Alternatively, especially in dry and in semi-arid regions, the actual implemented approach of minimizing infiltration might result in and promote fossilization, mummification, of the waste. It is not clear that the full implications of the likely extreme longevity of many wastes in many landfills are understood or have been addressed. They probably deserve more attention than they have received to date?

Unfortunately such approaches are expensive. Even though in recent decades considerable efforts have been devoted to study landfills in less-developed countries, it appears that landfill leachate control remains a low priority in many societies. Hence it seems rather likely that they will continue to receive low priority in many parts of the world, and will continue to pose serious risks and hazards.

Leachate quality significantly depends on the characteristics (e.g., chemical composition, physical structure) of emplaced waste. Hence leachate control certainly would be improved by implementing more rigorous controls on landfill input, although this most likely will remain a major challenge for municipal waste in particular. Presumably, as analytical instrumentation and tools continue to improve, it should eventually be possible to provide a better input characterization, and hence improved optimization of operational controls that affect leachate quality. How well

Landfill Leachate Control. Figure 9
Flow chart to determine monitoring requirements for landfill leachate control (Appendix I of ref [16] lists constituents, contaminants, for which testing is required) (From Ref. [16], Fig. 5-5, p. 278)

and reliable and comprehensively waste input can be controlled through regulatory means probably at least to some extent is a function of culture, citizen civic responsibility, and hence may vary across borders.

Liner and cover installations are labor intensive. It is to be hoped that technological improvements will continue, and will result in simpler and more reliable installation methods for these critical components of the leachate control system.

An obvious approach, in principle, to reduce landfill leachate control requirements is to reduce landfill leachate. Among the major methods that are being pursued toward this goal are recycling, composting, and waste incineration. In one way or another, all of these have been practiced and implemented to varying degrees and studied. All have benefits and shortcomings. It can be anticipated that all these methods will continue to be improved and find wider applications. This will reduce landfill requirements, undoubtedly one of the best methods to reduce leachate control requirements. An even more fundamental approach is the ongoing effort to minimize waste production in the first place.

Notwithstanding these efforts, all indications are that waste generation will continue to increase,

Landfill Leachate Control. Figure 10

Flow chart illustrating the decision making process as to whether remedial action is required as a result of monitored leachate content: excessive concentration of contaminants (Appendix I and/or Appendix II materials of Ref. [16]) in the effluent emanating from the landfill (From Ref. [16], Fig. 5-6, p. 284)

probably increase substantially. According to the Organisation for Economic Co-Operation and Development ([21], p. 235) "The annual generation of municipal waste in OECD countries increased by around 40% between 1980 and 1997," and is expected to increase by about 43% in the years 2000–2020 ([21], p. 236). The same source ([21], p. 237) expects that municipal solid waste generation in non-OECD

countries will increase, over the period 1995–2020, by somewhat over 100%. While recycling and, to a lesser extent incineration, are likely to continue to grow, it is expected that in 2020, landfill will still be used for 50% of municipal waste disposal in OECD countries and for 70% in non-OECD countries. According to OECD's updated 2008 projection ([22], p. 238), municipal solid waste generation in OECD countries is expected to increase by about 250% by 2030 compared to 1980, even though expected population growth over that period in these countries is likely to be only about 40%. Municipal solid waste generation is expected to grow much faster in the BRIICS countries (Brazil, Russia, India, Indonesia, China, and South Africa), and especially in the rest of the world, due to population growth and economic growth. Moreover, in many of the BRIICS countries, inappropriate collection and treatment of municipal waste remains widespread, estimated to range from 20% to, much more commonly, 60% of the waste. Presumably, the situation for the rest of the world most likely is worse. The need for improved and less expensive waste management and leachate collection and treatment are rather obvious. While the research that is going on in advanced societies is impressive in its sophistication, and unquestionably will greatly improve the leachate control with more advanced treatment options, one cannot help but see that most of these result in very expensive and technically challenging treatments. Might there not be a place for relatively inexpensive, even if less completely perfect treatment methods, that provide at least some improved control, at a cost less wealthy societies can afford?

Acknowledgments

Glossary

Landscape A geographic area in which variables of interest are spatially heterogeneous. The boundary of a landscape may be delineated based on geographic, ecological, or administrative units (e.g., a watershed, an urban area, or a county) which are relevant to the research questions and objectives.

Landscape connectivity The degree of a landscape to facilitate or impede the exchange of organisms, energy, material, and information among landscape elements. This is sometimes referred to as landscape functional connectivity, which is a function of both landscape structural connectivity and the movement characteristics of the species or process under consideration. Landscape structural connectivity is simply a measure of how spatially connected the elements in a landscape are, without reference to any particular ecological process.

Landscape ecology The science of studying and improving the relationship between spatial pattern and ecological processes in a landscape on multiple scales. Landscape ecology studies the structure, function, and dynamics of landscapes of different kinds, including natural, seminatural, agricultural, and urban landscapes.

Landscape fragmentation The breaking-up of landscape into smaller patches by anthropogenic and natural forces or the introduction of barriers that impede exchange of organisms, energy, material, and information across a landscape. Habitat fragmentation is a similar term to landscape fragmentation, but has a more explicit focus on changes in habitat relevant for organisms of interest.

Landscape pattern The composition (diversity and relative abundances) and configuration (shape, size, and spatial arrangement) of landscape elements, including both spatial patchiness and gradients.

Landscape function The horizontal and vertical exchanges of organisms, energy, material, and information in a landscape.

Landscape structure The composition and spatial arrangement of landscape elements – including patches, corridors, and the matrix.

Landscape dynamics Temporal changes in the structure and function of a landscape, driven by natural and anthropogenic processes.

Landscape sustainability The ability of a landscape to maintain its basic environmental, economic, and social functions under ever-changing conditions driven by human activities and environmental changes. Landscape sustainability emphasizes the optimization of the composition and spatial configuration of the landscape so as to achieve a high level of resilience or persistency.

Metapopulation The total population system that is composed of multiple local populations geographically separated but connected through dispersal.

Patch dynamics A perspective that ecological systems are mosaics of patches, each exhibiting nonequilibrium dynamics and together determining the system-level behavior. Patches can be biotic or abiotic, ranging from a tree gap in a forest or a resource patch in a grassland to a whole ecosystem or a continent.

Pattern analysis The procedures with which landscape pattern is quantified, primarily, using synoptic indices and spatial statistical methods.

Scale The spatial or temporal dimension of a phenomenon. In landscape ecology, scale usually refers to grain and extent. Grain is the finest spatial or temporal unit in a data set, within which homogeneity is assumed, whereas extent is the total spatial area or temporal duration of a study. Grain and resolution are two related but distinct concepts. In general, fine-grained analyses require high-resolution data, but high-resolution data, after rescaling or aggregation, can also be used for coarse-grained analyses.

Scaling The translation of information between or across spatial and temporal scales or organizational levels.

Spatial heterogeneity The combination of discrete and continuous variations of one or more variables in a landscape, which can be characterized as patchiness, gradients, or a mixture of both. Spatial heterogeneity varies with scale in space and time.

Spatially explicit models Models that explicitly take account of the locations of processes in a two- or three-dimensional space so that the spatial arrangement of landscape elements matters.

Definition of the Subject

Landscapes are spatially heterogeneous areas characterized by a mosaic of patches that differ in size, shape, contents, and history. When spatial heterogeneity is considered, the explicit treatment of scale becomes necessary and hierarchies emerge. Landscape ecology is the science of studying and improving the relationship between spatial pattern and ecological processes on a multitude of scales and organizational levels. In a broad sense, landscape ecology represents both a field of study and a scientific paradigm. As a highly interdisciplinary and transdisciplinary enterprise, landscape ecology integrates biophysical and analytical approaches with humanistic and holistic perspectives across natural and social sciences. Landscape ecology was initially developed in Europe. With theoretical developments in spatial ecology and technological advances in remote sensing and geospatial information processing, landscape ecology became an internationally recognized field of study in the 1980s. The most salient characteristics of landscape ecology are its emphasis on the pattern-process relationship and its focus on broad-scale ecological and environmental issues. Key research topics in landscape ecology include ecological flows in landscape mosaics (e.g., movements of water, nutrients, plant propagules, animals, and other materials), land use and land cover change, scaling, understanding the relationship between landscape pattern metrics and ecological processes, and landscape conservation and sustainability.

Introduction

Landscape ecology is an interdisciplinary field that aims to understand and improve the relationship between spatial pattern and ecological processes on a range of scales [1]. Although the term appeared in the 1930s, landscape ecology was not a recognized scientific field of global scope until the 1980s when remote sensing data and computers became widely accessible to ecologists and geographers. The 1980s was also a time period when ecological ideas of spatial heterogeneity and nonequilibrium dynamics flourished, and when landscape ecology took roots in North America. Today, landscape ecology is a well-established field of study, with active participation of ecological, geographical, and social scientists from around the world.

Landscape ecology has been dominated by two schools of thought: the European perspective and the North American perspective. At the risk of oversimplification, the European landscape ecology perspective may be considered as being characterized by a more holistic, humanistic, and society-centered view, with a focus on user-inspired and solution-driven research. The North American landscape ecology perspective, on the other hand, has been dominated by a more analytical and biological ecology–centered view, with a focus on basic science-oriented and question-driven studies. Cautions must be exercised, however, to avoid overinterpretation of such dichotomous characterization [2]. The two perspectives are neither inclusive nor exclusive; they are not contradictory but complementary. There are, and should be, other approaches to landscape ecology. For example, one may argue for an Australian landscape ecology perspective that focuses on pragmatic and functional approaches, typically, tied

with land management, restoration, and conservation issues (e.g., [3]).

Landscape ecology is now a well-established interdisciplinary field of study, which is evidenced by several characteristics. These include an evolving but identifiable system of concepts, theories, principles, methods, and applications, a hierarchy of professional organizations from the international association to local chapters, a flagship journal, Landscape Ecology (http://www.springerlink.com/content/0921-2973), the adoption in educational and training programs by major universities and research institutes around the world, and an increasing number of publications in main-stream scientific journals which indicate its recognized status as well as its expanding impacts on related disciplines.

In this entry, I focus on the key concepts, research topics, and quantitative methods in landscape ecology. A number of textbooks on landscape ecology are available where more details on the contents covered here can be found [4–8].

What is Landscape Ecology?

Diverse Concepts of Landscape

The term, "landscape," is a key concept in a number of fields, from social to geographical and ecological sciences. With the rise of landscape ecology in the past several decades, the concept of landscape has achieved a prominent status in the interdisciplinary literature. However, because of the plurality of its origins and interpretations, landscape has acquired various connotations. For example, the same word may refer to a natural landscape, a cultural landscape, a political landscape, an economic landscape, a mental landscape, an adaptive landscape, a landscape view, landscaping, or landscape painting [9, 10].

Even within the field of landscape ecology, the word, "landscape," has different meanings, and the differences usually hinge on the spatial scale and the contents of a landscape. For example, landscape has been defined as a kilometers-wide geographic area [11, 12], which corresponds to the "human-scale" landscape. This is the scale at which the field of landscape ecology was originally developed in Europe, and at which most landscape studies have been conducted around the world ever since. The human-scale landscape, in general, seems to coincide well with geographic units such as watersheds and urban regions [4], as well as spatial domains of human perception [13]. Thus, it resonates with the public, the decision makers, and researchers who are conscious about the environmental setting in which they live, work, and engage in recreation.

Many other landscape ecologists, however, have treated landscape as a multi-scale or hierarchical concept, meaning that a landscape is a spatially heterogeneous area that may be of various sizes, depending on the subject of study and the research questions at hand [6, 14, 15]. In this case, landscape is an "ecological criterion" [14], and its essence does not lie in its absolute scale but in its internal heterogeneity. Different plant and animal species perceive, experience, and respond to spatial heterogeneity at different scales, and patterns and processes in landscapes tend to have different characteristic scales [16]. Thus, a hierarchical concept of landscape, of course also encompassing the human-scale, is both sensible and necessary. Apparently, one does not need to consider a landscape of tens of square kilometers to study how grassland vegetation pattern affects the movement of beetles [17] or is affected by gophers [18].

The elements that constitute a landscape vary greatly in landscape ecological research. For simplicity, the components of a landscape may be classified as tangible versus intangible and biophysical versus cultural. This is not intended to represent a dichotomous view, but rather a continuum within which a variety of components coexist. Tress and Tress [10] proposed a "transdisciplinary landscape concept" that encompasses five dimensions: (1) landscape as a spatial entity, (2) landscape as a mental entity, (3) landscape as a temporal dimension, (4) landscape as a nexus of nature and culture, and (5) landscape as a complex system. Landscape ecological studies often have focused on some but not all of these dimensions. The concept of landscape provides a meeting ground for a number of disciplines, including archaeology, ecology, geography, geology, history, landscape architecture, and regional economics. To achieve its interdisciplinary and transdisciplinary goals, landscape ecology needs to appreciate and integrate the multifaceted perspectives on the culture-nature/people-place relationships that are offered by these diverse disciplines.

Evolving Concepts of Landscape Ecology

The definitions of landscape ecology are also diverse, although they are not quite as numerous as those of landscape (Table 1). Images can be powerfully inspiring, and this is especially true to someone who has a special interest in landscape patterns. Partly inspired by the conspicuous spatial patterns revealed in aerial photographs, the German geographer and botanist Carl Troll [19] coined the term "landscape ecology" and defined it later as "the study of the main complex causal relationships between the life communities and their environment in a given section of a landscape" [20, 21]. Carl Troll's training and research in multiple disciplines endowed him with the abilities to synthesize across, and innovate at the interface between, different fields. He was trained as a botanist; did his doctoral dissertation in plant physiology; and then spent decades working on the climatic, geologic, geographical, and ecological aspects of various landscapes in Europe, South America, and Africa. It is not difficult to understand why Troll could simultaneously appreciate the then-new idea of "ecosystem" put forward by Arthur Tansley [28], as well as the great potential for geospatial analysis presented by aerophotography. As a result of his attempt to integrate the "vertical" ecological approach with the "horizontal" geographical approach, a new field of study was born.

In the past several decades, landscape ecology has acquired a number of definitions which all are, in some way, related to Carl Troll's original definition. For example, Zonneveld [22] defined landscape ecology as "an aspect of geographical study which considers the landscape as a holistic entity, made up of different elements, all influencing each other." He advocated that the landscape should be studied as the "total character of a region," not "in terms of the separate aspects of its component elements" [22, 29]. This holistic landscape perspective continues and culminates in the work by Naveh [30], who described landscape ecology as the study of "the total spatial and functional entity of natural and cultural living space."

Some key ideas of contemporary landscape ecology, such as patch dynamics [31–33] and the patch-corridor-matrix model [11, 12], began to emerge in North America in the late 1970s, apparently with little connection to the European root. The early ideas of landscape ecology in North America were inspired by the theory of island biogeography [34], with an explicit focus on spatial heterogeneity. The first major communication between North American and European landscape ecologists occurred in 1981 when five American ecologists attended the first International Congress on Landscape Ecology in the Netherlands. Two years later, 25 ecologists (23 Americans, 1 Canadian, and 1 French) gathered at Allerton Park, Illinois of USA, to discuss the nature and future directions of landscape ecology. The report of this historic work, published in the following year [24], became an important guide to the incipient landscape ecologists in North America [35].

Why was such discussion necessary after landscape ecological research had been practiced for more than 40 years in Europe? The answer seems clear from Forman [36]: "What theory explains the spatial heterogeneity of energy, nutrients, water, plants, and animals at the level of a landscape, the setting in which we live? Alas, none." To develop such a landscape theory, broader scales that encompass multiple ecosystems need to be considered, and horizontal interactions have to be a focus of study. Thus, Forman and Godron [11, 12] defined landscape ecology as the study of the structure (spatial relationships among the distinctive landscape elements), function (flows of energy, materials, and species among landscape elements), and dynamics (temporal change in landscape structure and function) of landscapes. The main theme of landscape ecology in North America, with an unmistakable focus on spatial heterogeneity, was set in Risser et al. [24]:

- Landscape ecology focuses explicitly upon spatial pattern. Specifically, landscape ecology considers the development and dynamics of spatial heterogeneity, spatial and temporal interactions and exchanges across heterogeneous landscapes, influences of spatial heterogeneity on biotic and abiotic processes, and management of spatial heterogeneity.

Is landscape ecology a subdiscipline of ecology? The term itself apparently suggests that it is. Many ecologists do consider landscape ecology as a branch of ecology (e.g., [6]), and most ecology programs of

Landscape Ecology. Table 1 A list of definitions of landscape ecology

Definition	Source
The German geographer Carl Troll coined the term "landscape ecology" in 1939, and defined it in 1968 as "the study of the main complex causal relationships between the life communities and their environment in a given section of a landscape. These relationships are expressed regionally in a definite distribution pattern (landscape mosaic, landscape pattern) and in a natural regionalization at various orders of magnitude" (Troll 1968; cited in Troll 1971)	• Troll [19] • Troll [20] • Troll [21]
"Landscape ecology is an aspect of geographical study which considers the landscape as a holistic entity, made up of different elements, all influencing each other. This means that land is studied as the 'total character of a region', and not in terms of the separate aspects of its component elements" (Zonneveld 1972)	• Zonneveld [22]
"Landscape ecology is a young branch of modern ecology that deals with the interrelationship between man and his open and built-up landscapes" based on general systems theory, biocybernetics, and ecosystemology (Naveh and Liberman 1984). "Landscapes can be recognized as tangible and heterogeneous but closely interwoven natural and cultural entities of our total living space," and landscape ecology is "a holistic and transdisciplinary science of landscape study, appraisal, history, planning and management, conservation, and restoration" (Naveh and Liberman 1994)	• Naveh and Lieberman [5] • Naveh and Lieberman [23]
"A landscape is a kilometers-wide area where a cluster of interacting stands or ecosystems is repeated in similar form; landscape ecology, thus, studies the structure, function and development of landscapes" (Forman 1981). Landscape structure refers to "the spatial relationships among the distinctive ecosystems;" landscape function refers to "the flows of energy, materials, and species among the component ecosystems;" and landscape change refers to "the alteration in the structure and function of the ecological mosaic over time" (Forman and Godron 1986).	• Forman [11] • Forman [12]
"Landscape ecology focuses explicitly upon spatial pattern. Specifically, landscape ecology considers the development and dynamics of spatial heterogeneity, spatial and temporal interactions and exchanges across heterogeneous landscapes, influences of spatial heterogeneity on biotic and abiotic processes, and management of spatial heterogeneity" (Risser et al. 1984). "Landscape ecology is not a distinct discipline or simply a branch of ecology, but rather is the synthetic intersection of many related disciplines that focus on the spatial-temporal pattern of the landscape" (Risser et al. 1984).	• Risser et al. [24]
"Landscape ecology emphasizes broad spatial scales and the ecological effects of the spatial patterning of ecosystems" (Turner 1989).	• Turner [25]
"Landscape ecology is the study of the reciprocal effects of the spatial pattern on ecological processes," and "concerns spatial dynamics (including fluxes of organisms, materials, and energy) and the ways in which fluxes are controlled within heterogeneous matrices" (Pickett and Cadenasso 1995).	• Pickett and Cadenasso [14]
"Landscape ecology investigates landscape structure and ecological function at a scale that encompasses the ordinary elements of human landscape experience: yards, forests, fields, streams, and streets" (Nassauer 1997).	• Nassauer [26]
Landscape ecology is "ecology that is spatially explicit or locational; it is the study of the structure and dynamics of spatial mosaics and their ecological causes and consequences" and "may apply to any level of an organizational hierarchy, or at any of a great many scales of resolution" (Wiens 1999).	• Wiens [27]

Landscape Ecology. Table 1 (Continued)

Definition	Source
"Landscape ecology emphasizes the interaction between spatial pattern and ecological process, that is, the causes and consequences of spatial heterogeneity across a range of scales" (Turner et al. 2001). "Two important aspects of landscape ecology . . . distinguish it from other subdisciplines within ecology": "First, landscape ecology explicitly addresses the importance of spatial configuration for ecological processes" and "second, landscape ecology often focuses on spatial extents that are much larger than those traditionally studied in ecology, often, the landscape as seen by a human observer" (Turner et al. 2001).	• Turner [6]
"Landscape ecology is the science and art of studying and influencing the relationship between spatial pattern and ecological processes across hierarchical levels of biological organization and different scales in space and time."	• Wu and Hobbs [1]

major research universities worldwide now offer courses in landscape ecology. On the other hand, Zonneveld [22] indicated that landscape ecology is not part of biological sciences, but a branch of geography. Risser et al. [24] contemplated three ways in which landscape ecology may be viewed: as an intersection of many disciplines, as a separate discipline, or as a branch of ecology. They concluded that only the first option was "intellectually and practically the most persuasive." They further pointed out that "viewing landscape ecology as an interdisciplinary field of research avoids the issue of which discipline 'owns' landscape ecology" (a problem that may have hindered the healthy development of some interdisciplinary fields, such as human ecology, for which geography, sociology, and anthropology all have claimed ownership). The Allerton workshop report clearly recognized the importance of the multidimensionality of landscapes and the interdisciplinarity of landscape ecology:

- A major forcing function of landscapes is the activity of mankind, especially associated cultural, economic, and political phenomena. . . . Landscape ecology is not a distinct discipline or simply a branch of ecology, but rather is the synthetic intersection of many related disciplines that focus on the spatial-temporal pattern of the landscape" [24].

Today, a general consensus seems to have emerged that landscape ecology is not simply an academic discipline, but rather a highly interdisciplinary field of study [2, 37]. Landscape ecology is an interdisciplinary and transdisciplinary science that focuses on the relationship between spatial pattern and ecological processes across scales. The goal of landscape ecology is not only to understand this relationship but also to influence it so as to help achieve landscape sustainability [38–40]. As such, a pluralistic and hierarchical framework has been proposed to facilitate synergistic interactions between biophysical/pattern-process and holistic/humanistic perspectives (Fig. 1) [37, 38]. "Hierarchical" here refers to the varying degrees of interdisciplinary, the hierarchy of organizational levels, and the multiplicity of spatiotemporal scales of landscape ecological studies. "Pluralistic" indicates the necessity and importance of recognizing and valuing the different perspectives and methods in landscape ecology due to its diverse origins and goals.

Key Research Topics Landscape Ecology

Based on the suggestions by a group of leading landscape ecologists (Table 2), Wu and Hobbs [2] identified six key issues that characterize landscape ecology: (1) interdisciplinarity or transdisciplinarity, (2) integration between basic research and applications, (3) Conceptual and theoretical development, (4) education and training, (5) international scholarly communication and collaborations, and (6) outreach and communication with the public and decision makers. Wu and Hobbs [2] also summarized ten key research topics and priorities as follows:

1. Ecological flows in landscape mosaics: A primary goal of landscape ecology is to understand the reciprocal relationship between spatial pattern and ecological processes [14]. Understanding the mechanisms of flows of organisms, energy,

Landscape Ecology. Figure 1
A schematic representation of a hierarchical and pluralistic view of landscape ecology (Modified from [38])

material, and information in landscape mosaics is central to landscape ecology. In particular, the study of the effects of spatial pattern on population and ecosystem processes has made much progress in the past several decades. There is a need to integrate socioeconomic theory of landscape change into metapopulation models to make them more relevant to the issues of biodiversity conservation and landscape sustainability. The spread of invading species has become an increasingly important ecological and economic problem which deserves more research efforts.

2. Causes, processes, and consequences of land use and land cover change: Land use and land cover change is arguably the most important driver for changes in the structure and function of landscapes. Land use and land cover change is driven primarily by socioeconomic forces, and is one of the most important and challenging research areas in landscape ecology. Numerous studies have been carried out to investigate the effects of land use and land cover change on biodiversity and ecological flows in human-dominated landscapes. More research efforts are needed to incorporate the insights of economic geography which studies how economic activity is distributed in space and resource economics which determines how land will be used [41]. Long-term landscape changes induced by economic activities and climate change, as well as "land use legacies" (i.e., the types, extents, and durations of persistent effects of prior land use on ecological patterns and processes) need to be emphasized in future research.
3. Nonlinear dynamics and landscape complexity: Landscapes are spatially extended complex systems which exhibit emergent properties, phase transitions, and threshold behavior. To understand the complexity of landscapes, concepts and methods from the science of complexity and nonlinear dynamics should be helpful.

Landscape Ecology. Table 2 A list of major research topics in landscape ecology suggested by a group of leading landscape ecologists from around the world at the 16th Annual Symposium of the US Regional Association of the International Association for Landscape Ecology, held at Arizona State University, Tempe, in April 2001 [2]

Development of theory and principles	• Landscape mosaics and ecological flows • Land transformations • Landscape sustainability • Landscape complexity
Landscape metrics	• Norms or standards for metric selection, change detection, etc. • Integration of metrics with holistic landscape properties • Relating metrics to ecological processes • Sensitivity to scale change
Ecological flows in landscape mosaics	• Exchanges of organisms, material, energy, and information across the landscape • Effects of connectivity, edges, and boundaries • Spread of invading species • Spatial heterogeneity and ecosystem processes • Disturbances and patch dynamics
Optimization of landscape pattern	• Optimization of land use pattern • Optimal management • Optimal design and planning • New methods spatial optimization
Metapopulation theory	• Integration of the view of landscape mosaics • Incorporation of socioeconomic factors and management decisions
Scaling	• Extrapolating information across heterogeneous landscapes • Development of scaling theory and methods • Derivation of empirical scaling relations for landscape pattern and processes
Complexity and nonlinear dynamics of landscapes	• Landscapes as spatially extended complex systems • Landscapes as complex adaptive systems • Thresholds, criticality, and phase transitions • Self-organization in landscape structure and dynamics
Land use and land cover change	• Biophysical and socioeconomic drivers and mechanisms • Ecological consequences and feedbacks • Long-term landscape changes driven by economies and climate changes
Spatial heterogeneity in aquatic systems	• The relationship between spatial pattern and ecological processes in lakes, rivers, and oceans • Terrestrial and aquatic comparisons
Landscape-scale experiments	• Experimental landscape systems • Field manipulative studies • Scale effects in experimental studies
New methodological developments	• Integration among observation, experimentation, and modeling • New statistical and modeling methods for spatially explicit studies • Interdisciplinary and transdisciplinary approaches
Data collection and accuracy assessment	• Multiple-scale landscape data • More emphasis on collecting data on organisms and processes • Data quality control • Metadata and accuracy assessment
Fast changing and chaotic landscapes	• Rapidly urbanizing landscapes • War zones • Other highly dynamic landscapes

Landscape Ecology. Table 2 (Continued)

Landscape sustainability	• Developing operational definitions and measures that integrate ecological, social, cultural, economic, and aesthetic components • Practical strategies for creating and maintaining landscape sustainability
Human activities in landscapes	• The role of humans in shaping landscape pattern and processes • Effects of socioeconomic and cultural processes on landscape structure and functioning
Holistic landscape ecology	• Landscape ecology as an anticipative and prescriptive environmental science • Development of holistic and systems approaches

For example, self-organization, percolation theory, complex adaptive systems (CAS), fractal geometry, cellular automata, and genetic algorithms have been used in the study of spatiotemporal dynamics of landscapes (e.g., [42–46]). However, the theoretical potential and practical implications of these concepts and methods are yet to be fully explored.

4. Scaling: Scaling refers to the translation of information from one scale to another across space, time, or organizational levels. Spatial scaling, in particular, is essential in both the theory and practice of landscape ecology because spatial heterogeneity does not make any sense without the consideration of scale [47]. While scale effects are widely recognized in landscape ecology, scaling-up or scaling-down across heterogeneous landscapes remains a grand challenge in landscape ecology and beyond [48]. General rules and pragmatic methods for scaling landscape patterns and processes need to be developed and tested.
5. Methodological advances: Landscape variables are often spatially autocorrelated and spatially dependent, which poses serious challenges for using traditional statistical methods based on the assumption of independence of observations. The spatial autocorrelation and dependence that traditional statistical methods try to get rid of are usually what landscape analyses intend to get at. Thus, spatial statistical methods that directly deal with spatial autocorrelation and dependence have increasingly been used in landscape ecology. Also, most landscape ecological problems need to be studied over large and multiple scales in a spatially explicit manner. This need poses problems such as the lack of replicability or "pseudoreplication" [49]. To get to the processes and mechanisms of landscape phenomena, landscape ecology has developed a suite of spatially explicit modeling approaches [50, 51]. In both spatial analysis and modeling of landscapes, remote sensing and GIS (geographic information systems) have become indispensable.
6. Relating spatial pattern measures to ecological processes: To understand the relationship between pattern and process, quantifying landscape pattern is necessary. Indeed, landscape pattern analysis has been a major part of landscape ecological research for the last few decades. A number of landscape metrics (Table 3) and spatial statistical methods have been developed and applied for describing and comparing the spatial patterns of landscapes, monitoring and predicting changes in landscape patterns, and relating spatial pattern to ecological processes at a particular scale or across a range of scales [47, 53, 54]. Nevertheless, a sound ecological understanding of these spatial analysis methods is yet to be fully developed [55].
7. Integrating humans and their activities into landscape ecology: Socioeconomic processes are the primary drivers for land use and land cover change which in turn determines the structure, function, and dynamics of most landscapes. Social and economic processes have increasingly been integrated into landscape ecological studies. The need for incorporating humans, including their perceptions, value systems, cultural traditions, and socioeconomic activities, into landscape ecology has made it a highly interdisciplinary and transdisciplinary enterprise [38, 56]. That said, effectively integrating human-related processes into ecology may remain one of the

Landscape Ecology. Table 3 Some commonly used landscape metrics [4, 52]

Landscape metric	Abbreviation	Description
Patch shape index	PSI	A measure for the complexity of the shape of a given patch: $PSI = \frac{P}{2\sqrt{A\pi}}$ where P is the perimeter of a patch, and A is the area of the patch. $PSI = 1$ for circles; $PSI = 1.1283$ for squares; and $PSI = 1.1968$ for a rectangle (2 L by L). $1/D$ is called "compactness" (see Forman [4]).
Perimeter/area ratio	PAR	A measure of the complexity of the shape of a patch: $PAR = P/A$ where P is the perimeter of a patch, and A is the area of the patch.
Number of patches	NP	The total number of patches in the landscape.
Patch density	PD	The number of patches per square kilometer (i.e., 100 ha).
Total edge	TE	The sum of the lengths of all edge segments (unit: meter).
Edge density	ED	The total length of all edge segments per hectare for the class or landscape of consideration (unit: m/ha).
Patch richness	PR	The number of different patch types in the landscape.
Patch richness density	PRD	The number of patch types per square kilometer (or 100 ha).
Shannon's diversity index	SHDI	A measure of patch diversity in a landscape that is determined by both the number of different patch types and the proportional distribution of area among patch types: $H = -\sum_{i=1}^{m} p_i \ln(p_i)$ where m is the total number of patch types and p_i is the proportion of the landscape area occupied by patch type i.
Dominance index	D	A measure of the degree of dominance by one or a few patch types in a landscape: $D = H_{\max} + \sum_{i=1}^{m} p_i \ln p_i$ where $H_{\max}$ is the maximum diversity when all patch types are present in equal proportions, m is the total number of patch types, and p_i is the proportion of the landscape area occupied by patch type i. Small values of D tend to indicate landscapes with numerous land use types of similar proportions.
Largest patch index	LPI	The ratio of the area of the largest patch to the total area of the landscape (unit: percentage).
Mean patch size	MPS	The average area of all patches in the landscape (unit: ha).
Patch size standard deviation	PSSD	The standard deviation of patch size in the entire landscape (unit: ha).
Patch size coefficient of variation	PSCV	The standard deviation of patch size divided by mean patch size for the entire landscape (unit: percentage).
Landscape shape index	LSI	A modified perimeter/area ratio of the form: $LSI = \frac{0.25E}{\sqrt{A}}$ where E is the total length of patch edges and A is the total area of the landscape (unitless).

Landscape Ecology. Table 3 (Continued)

Landscape metric	Abbreviation	Description
Mean patch shape index	MSI	A patch-level shape index averaged over all patches in the landscape: $MSI = \frac{\sum_{i=1}^{m}\sum_{j=1}^{n}\left[\frac{0.25P_{ij}}{\sqrt{a_{ij}}}\right]}{N}$ where P_{ij} and a_{ij} are the perimeter and area of patch ij, respectively, and N is the total number of patches in the landscape (unitless).
Area-weighted mean patch shape index	AWMSI	Mean patch shape index weighted by relative patch size: $AWMSI = \sum_{i=1}^{m}\sum_{j=1}^{n}\left[\left(\frac{0.25P_{ij}}{\sqrt{a_{ij}}}\right)\left(\frac{a_{ij}}{A}\right)\right]$ where P_{ij} and a_{ij} are the perimeter and area of patch ij, respectively, A is the total area of the landscape, m is the number of patch types, and n is the total number of patches of type i (unitless).
Double-log fractal dimension	DLFD	The fractal dimension for the entire landscape which is equal to 2 divided by the slope of the regression line between the logarithm of patch area and the logarithm of patch perimeter: $DLFD = \frac{2}{\left[\frac{\left[N\sum_{i=1}^{m}\sum_{j=1}^{n}\left(\ln(P_{ij})\ln(a_{ij})\right)\right]-\left[\left(\sum_{i=1}^{m}\sum_{j=1}^{n}\ln(a_{ij})\right)\right]}{\left(N\sum_{i=1}^{m}\sum_{j=1}^{n}\left(\ln(P_{ij}{}^{2})\right)\right)-\left(\sum_{i=1}^{m}\sum_{j=1}^{n}\ln(P_{ij})\right)^{2}}\right]}$ where P_{ij} and a_{ij} are the perimeter and area of patch ij, respectively, m is the number of patch types, n is the total number of patches of type i, and N is the total number of patches in the landscape (unitless).
Mean patch fractal dimension	MPFD	The average fractal dimension of individual patches in the landscape, which is the summation of fractal dimension for all patches divided by the total number of patches in the landscape: $FD = \frac{\sum_{i=1}^{m}\sum_{j=1}^{n}\left(\frac{2\ln(0.25P_{ij})}{\ln(a_{ij})}\right)}{N}$ where P_{ij} and a_{ij} are the perimeter and area of patch ij, respectively, m is the number of patch types, n is the total number of patches of type i, and N is the total number of patches in the landscape (unitless).
Area-weighted mean patch fractal dimension	AWMFD	The patch fractal dimension weighted by relative patch area: $AWMPED = \sum_{i=1}^{m}\sum_{j=1}^{n}\left(\frac{2\ln(0.25P_{ij})}{\ln(a_{ij})}\left(\frac{a_{ij}}{A}\right)\right)$ where P_{ij} and a_{ij} are the perimeter and area of patch ij, respectively, m is the number of patch types, n is the total number of patches of type i, and A is the total area of the landscape (unitless).
Contagion	CONT	An information theory–based index that measures the extent to which patches are spatially aggregated in the landscape [57]: $CONT = \left[1+\sum_{i=1}^{m}\sum_{j=1}^{m}p_{ij}\ln(p_{ij})/2\ln(m)\right](100)$ where p_{ij} is the probability that two randomly chosen adjacent pixels belong to patch type i and j, m is the total number of patch types in the landscape (unitless).

ultimate challenges for landscape ecologists in years to come.

8. Optimization of landscape pattern: If spatial pattern significantly influences ecological processes in the landscape, then there must be certain patterns that are better than others in terms of promoting ecosystem functioning and services. This is a question of landscape pattern optimization (e.g., optimization of land use pattern, optimal landscape management, optimal landscape design, and planning). For example, can landscape patterns be optimized in terms of both the composition and configuration of patches and matrix characteristics to maximize biodiversity and ecosystem services? Are there optimal ways of "spatially meshing nature and culture" to promote landscape sustainability? These are some of the challenging questions that landscape ecologists ought to address now and in the future. Spatial optimization of landscape pattern for environmental purposes presents exciting research opportunities and requires interdisciplinary approaches.
9. Landscape conservation and sustainability: Biodiversity, ecosystem functions, and human activities, all take place in landscapes. Landscape fragmentation profoundly alters ecological and socioeconomic processes. Thus, the importance of applying landscape ecological principles in biodiversity conservation and sustainable development has been increasingly recognized. However, specific landscape ecological guidelines for biodiversity conservation are needed, and a comprehensive and operational definition of landscape sustainability is yet to be developed.
10. Data acquisition and accuracy assessment: Landscape ecological studies use large-scale and multiscale data. A suite of advanced technologies are readily available, including various remote sensing techniques, GIS, GPS (global positioning systems), and spatial analysis and modeling approaches. However, ecological understanding of species and ecosystems is essential in landscape ecology, and this requires the collection of basic biological data of landscapes. Also, to ensure the quality of landscape data, error analysis, uncertainty analysis, and accuracy assessment have become a key issue in landscape ecological research.

Future Directions

Landscape ecology is a highly interdisciplinary field of study which is characterized, most conspicuously, by its spatial explicitness in dealing with ecological problems in theory and practice. Emphasis on spatial heterogeneity begs questions of the pattern-process relationships and scale. Studying spatial pattern without relating it to ecological processes is superficial, and investigating ecological processes without consideration of spatial pattern is incomplete. From this perspective, landscape ecology is a science of heterogeneity and scale, providing a new scientific paradigm for ecology and other related fields.

On the other hand, with increasing human dominance in the biosphere, emphasis on broad spatial scales makes it inevitable to deal with humans and their activities. As a consequence, humanistic and holistic perspectives have been and will continue to be central in landscape ecological research. Thus, landscape ecology has become increasingly relevant to sustainability research and practice [38, 56]. First, landscape ecology provides a hierarchical and integrative ecological basis for dealing with issues of biodiversity and ecosystem functioning from fine to broad scales. Second, landscape ecology has already developed a number of holistic and humanistic approaches to studying nature–society interactions. Third, landscape ecology offers theory and methods for studying the effects of spatial configuration of biophysical and socioeconomic component on the sustainability of a place. Fourth, landscape ecology has developed a suite of pattern metrics and indicators which can be used for quantifying sustainability in a geospatially explicit manner. Finally, landscape ecology provides both theoretical and methodological tools for dealing with scaling and uncertainty issues that are fundamental to most nature–society interactions.

To move forward, future landscape ecological studies need to further address the key research topics as discussed earlier in this entry. In addition, concerted efforts need to be made to focus on sustainability-related research questions. For example, what theories, principles, and methods of landscape ecology are pertinent to sustainability and how can they be operationalized? How does landscape pattern or spatial heterogeneity affect sustainability? How do ecological,

economic, and social patterns and processes in landscapes change with scale and interact to influence sustainability? How is landscape sustainability measured and what roles can landscape metrics play in all this? How can landscape models to project sustainability trajectories in response to environmental, economic, social, and institutional changes be developed? And finally, how can landscape ecology help design sustainable landscapes?

Glossary

Development plan A document (often consisting of several written documents and maps) that aims at organizing the spatial development in a particular territory in a comprehensive manner; the term

development plan has different meanings in different legal and administrative contexts, in many countries it is used for indicative rather than compulsory plans that complement land use planning by addressing additional aspects of spatial development (e.g., infrastructure planning).

Density, urban density Urban densities are measured by the number of people (or housing units, floor space, jobs) per unit urban land (e.g., km, hectare, acre); density is an important measure of urban form; the density of a lot, a neighborhood, or city usually indicates the intensity of urban land uses.

Green belt Idea of retaining an area of largely undeveloped, agricultural, or wild or park land surrounding an urban settlement.

Greenfield development Urban development that occurs on previously nonurban (agricultural, forestry, pasture, or other) land (as opposed to brownfield development that occurs on derelict sites); synonym of land consumption.

Growth management A set of policies and interventions used by governments at different tiers to ensure that urban growth occurs in a controlled and sustainable way; the containment of urban growth to counteract urban sprawl, the sufficient supply with urban services, and the protection of valuable land resources are the most important aims of growth management programs.

Land consumption Conversion of land use from nonurban (agricultural, forestry, pasture, or other) to urban uses (mainly residential, industrial, commercial, and transport); the term has a pejorative connotation.

Land cover The observed biophysical cover on the earth's surface, usually expressed in terms of vegetation cover or lack of it; land cover changes can occur as the conversion from one class of land cover to another or as a changing condition within a land cover class.

Land use Human employment of land; land use is characterized by the arrangements, activities, and inputs undertaken by humans in order to use land for productive or reproductive purposes; urban land use change can be attributed to the change of use from a land use class to another or to varying intensities within a land use class.

Land use pattern Spatial configuration of land uses or patches.

Land use plan Product of land use planning that is usually legally binding and prescribes how a piece of land can (and how it must not) be used.

Land use planning Any systematic effort of public authorities to organize (or at least influence) the way people, that is, society, make use of the land.

Spatial planning Any systematic effort of public authorities to organize, that is, influence the pattern of spatial organization of society. (Spatial planning is often used as a synonym of land use planning but can be seen as the broader term that also includes sector-specific planning, e.g., the planning and allocation of infrastructures.)

Suburbanization Suburbanization occurs when the growth of the suburbs (population, employment) dominates that of the central city; suburbanization is driven by relocation decisions of private households and firms leaving the central parts of metropolitan areas in favor of suburban, less dense, and cheaper lands; at the same time, suburbanization can also be caused by in-migration from outside the metropolitan area to the suburban parts.

Urban design plan A specific kind of land use plan, which, according to the planning system of many countries, formulates detailed norms for the land use of smaller areas (e.g., a couple of building blocks); urban design plans are often drawn up for areas that are about to be developed or fundamentally restructured.

Urbanization An increase in the proportion of the population living in urban areas or cities (urban systems).

Urban sprawl A specific, mostly unintended, pattern of land use that exhibits low-density residential and commercial settlements, the spatial segregation of certain land use types in specialized zones, and a spatially discontinuous urban expansion; in metropolitan areas, both in developed and developing countries, urban sprawl is the dominating spatial manifestation of land consumption.

Urban growth boundary (UGB) Line, defined by land use planning, which circumscribes an entire urbanized area and mandates that the area inside the boundary is to be used for higher density urban

development and the area outside for lower density development.

Urban system Human settlements with a minimum population density.

Zoning The practice of designating permitted uses of land to particular areas that are unambiguously separated from each other; zoning is usually enacted via land use plans and primarily aims at segregating uses that are thought to be incompatible.

Definition and Relevance of the Subject

Land use-driven environmental degradation has long been considered a locally scaled phenomenon. Today, the global dimension of land use related environmental change is generally acknowledged by researchers and policy makers [1–4]. The need to provide a still growing world population with housing, food, fiber, and freshwater accompanied with wasteful land use practices has resulted in a cumulative loss of biologically productive land and ecosystem functions. Moreover, land use practices are directly or indirectly responsible for the chemical degradation of environmental resources and high levels of greenhouse gases. Thus, land use has become a more and more important agent of global change that influences fundamental environmental processes. Foley et al. [1, p 572] rightly point out that modern land use processes allow humans to increase the short-term supply of material goods but undermine ecosystem services in the long run on regional and global scales.

Urbanization or – more specifically – land consumption as the conversion of land use from nonurban to urban uses is only a part of land use-driven environmental degradation processes. And it may not be the most important one with respect to the loss of productive land and ecosystem services. Between 0.3% and 4% of the earth's land surface is occupied by impervious or built-up surfaces [2, 4–7]. The pervasive effects of forest clearance, subsistence agriculture, and intensified farmland production are perhaps more important for the ongoing loss of the world's biological resources (Fig. 1). However, when taking the many indirect impact pathways of urban land uses into account (e.g., fragmentation of natural landscapes and habitats, chemical degradation of hydrological systems by polluted urban runoff, roads affecting adjacent habitats by noise), urbanization must be regarded as an important causative factor in models of global and regional environmental change [8].

In addition, there are strong links between urbanization levels and the intensity of rural land use, be it through land-consuming urban lifestyles (tourism and recreational activities, second homes), the relocation of unwanted land uses to the city edge or even peripheral locations (airports, wastewater sites, etc.), or the

Landscape Planning for Minimizing Land Consumption. Figure 1
Stages of land use transition in human history [1]

demand for facilities that serve the increased intensity of production and energy flows between rural and urban communities (transport infrastructure, warehousing, biofuel production, solar parks, wind parks). Land consumption goes against the objectives of sustainable development in two ways: (1) by increasing the ecological footprint through the addition of land with resource consumptive human activities and (2) by reducing the biocapacity of a region or a country.

At the same time, blaming land consumption for urban purposes as environmentally harmful and generally non-sustainable would be an inappropriate simplification. The phenomenon of urban growth confronts human societies with an intrinsic dilemma. On the one hand, the continuous development of land for residential or commercial purposes is absolutely essential for demographically and economically growing nations [9]. On the other hand, land-consuming human activities degrade ecosystem services upon which demographically growing societies strongly depend. Adding to the dilemma, land-intensive modes of urban growth often represent people's preferences for greener, less dense, and automobile-oriented communities.

While global land use change has become a hot topic over the past few years, urbanization, suburbanization, and urban sprawl at regional and local scales have been the subjects of long-standing academic discussions. Over the years, improving standards of living, the increase in personal mobility, the industrialization of agriculture, the ongoing land demand by households and firms, together with vast changes in societal norms and values have led to widespread conflicts over the use of land [10]. Land consumption changes the physical performance of urban systems in a variety of ways. Among them, the increase in artificial surfaces, the change in densities, and the alteration of land use patterns are the most important ones. Land consumption is being blamed for its contribution to the degradation of natural and seminatural habitats and its stimulating effects on motorized transportation. Consequently, concerns have arisen on the role of changing urban forms for rising greenhouse gas emissions and climate change [11–13]. Moreover, in the recent past other impacts attracted consideration, such as the negative implication of low-density environments on physical activity levels and health outcomes (e.g., [14]).

Recent policy initiatives have further fuelled interest in this subject. In the USA, a number of states have adopted growth management programs that aim at containing urban growth and preserving valuable open space. The English government has set a national target to deliver 60% of all new housing units on previously developed land and through conversions of the existing building stock. The government regards the reuse of urban land a key policy to reduce the development pressure on the open countryside and to improve urban regeneration by upgrading physically and socially deprived cities and neighborhoods with new housing and urban services of higher quality [15]. The Chinese government, concerned about the alarming loss of prime farmland due to urbanization, has introduced regulative policies that aim to protect farmland more effectively [16]. The German federal government introduced a national target to reduce the rate of conversion of nonurban to urban land uses from 130 ha per day in 2000 to 30 ha per day in 2020 [17]. The government argues that land consumption and landscape fragmentation, important aspects of "urban sprawl," are to be acknowledged as key drivers of species loss, landscape deterioration, and the decline of infrastructure efficiency.

While the effectiveness of these legislations and policy initiatives is subject to a highly controversial dispute (e.g., [18–21]), their sheer existence has stimulated further research into the nature of urban expansion patterns, their environmental, social, and economic impacts, and more effective anti-sprawl strategies and policies.

Introduction

Public concern over the undesirable effects of urban growth and land consumption can be traced back to an era when the "exploding metropolis" and its radically changing land use patterns and urban design first became physically visible. The beginning suburbanization process at a metropolitan scale was accompanied by an unprecedented expansion of development at the expense of open space and natural land resources. Not surprisingly, the debate on the unintended effects of urban growth started in the USA where rising affluence, a rapid motorization, public funds for low-density housing, and an antiurban social

climate ("white flight") had formed the precondition for a "mass movement" from the central cities to suburban areas – much earlier than in Europe or other parts of the world. In a 1937 speech to US urban planners, Earl Draper, Director of Tennessee Valley Authority, first used the term "sprawl" to indicate a specific pattern of urban growth that makes the countryside – from his point of view – "ugly, uneconomic [in terms] of services and doubtful social value" (cited from [22]). Since then, the discussion about the impacts of urban sprawl as well as its drivers and remedies has continued (see [23–27] as early contributions) and spread around the globe. Today, urban sprawl and its counterpart, the "compact city," are subject to scientific and political discourses in many developed *and* developing countries (see [28–34] as a few more recent examples).

This debate has clearly broadened its scope and increased in intensity over the decades. The major topics that characterized the debate on urban sprawl before the 1980s had already been established before the Second World War, notably the effects on ecosystem services and landscape beauty, on transportation and the efficiency of network infrastructure [35]. In the last two decades, however, researchers have made substantial progress in empirically addressing spatial manifestations, drivers, and effects of land-consuming human activities as well as the effectiveness of anti-sprawl policies and instruments. As a consequence, the global dimension of land consumption and urban sprawl (as noted above) is now on the agenda of policy makers and researchers worldwide.

Despite the fact that we know much more about the nature of land consumption and its complex societal roots today, many research questions still need to be addressed. On the one hand, it can be said that the quality of information regarding past trends in land use change has significantly improved over the decades, mainly due to the availability of new data sources like remotely sensed data. Likewise, thorough knowledge has been acquired on the many different and complex impacts of land consumption. On the other hand, forecasting future land consumption remains a scientific challenge. Current state-of-the-art prediction models often have to deal with unreliable data, their use is therefore limited to the definition of alternative scenarios within the ranges of uncertainty. In addition, there is still considerable scope for the deepening of scientific knowledge on the driving forces and dynamics of land-consuming developments [36, p 45f].

Apart from these methodological and conceptual challenges, the lack of internationally comparative data on urban land use prevents scientists from analyzing the influence of region-specific political and cultural factors on the spatial formation of urban growth. In this context, research on urban sprawl is largely limited to case studies of selected metropolitan areas in a national context that have limited value for the comparison of regional policies or housing preferences. While economic and population trends are often subject to international cross-sectional research efforts and are therefore well-documented, virtually no information exists on the amounts, rates, and patterns of urban expansion across countries and their metropolitan areas. It has only been in the recent past that empirical studies systematically addressed similarities and dissimilarities in urban land use change across world regions and countries [2, 8, 37–39].

Based on this problem description, this contribution aims to provide a comprehensive overview on the debate on land consumption and its importance for related thematic fields in spatial planning, that is, urban and regional planning as well as environmental and conservation planning. It starts with an elaboration of the meaning of "land consumption" in terms of terminology, causations, and consequences (Section on "A Conceptualization of Land Consumption"). Then, it provides an account of how spatial planning can try to control land consumption, thereby introducing a taxonomy of planning strategies and instruments that appear suited to minimize land consumption (Section on "The Means of Spatial Planning to Minimize Land Consumption"). The contribution concludes with a brief outlook on future challenges regarding both planning practices as well as scientific efforts that endeavor to get a grip on land consumption, either in reality or conceptually (Section on "Future Directions").

A Conceptualization of Land Consumption

What is Land Consumption?

Land consumption, sometimes referred to as land take [38, 40, p 308] can be regarded as a subprocess of land

use change marked by a conversion from nonurban to urban land use types. The visible outcome of land consumption is the spatial expansion of built-up areas accompanied by a significant alteration of land cover features and urban form. The construction of new buildings and infrastructure facilities, the sealing of surfaces and other modifications of the original land surface usually result in a decline of environmental quality. Clearly, it is not land that is consumed. The term "consumption" solely refers to the mostly irreversible loss of ecosystem services (or even entire ecosystems) due to the physical modification of land cover.

In terms of environmental significance, the size of urban areas by itself would be a very poor indicator for the impact of urban land use [6]. In order to adequately address land consumption in terms of its negative (or positive) effects in this context,

- The previous use of land and land cover (agricultural, forestry, or natural)
- The dominant purpose of new urban use (residential, commercial, industrial, recreational, or others) and the corresponding land cover features such as the imperviousness of surfaces
- The location and pattern of new urban land and
- The efficiency of land use

have to be taken into account [8]. To put it bluntly, the development of an acre or hectare of new residential land on former agricultural land has not the same impact as the development of an acre or hectare of industrial land on a drained wetland site. New development in the vicinity of existing settlements has clearly fewer negative impacts on the landscape matrix than the development of many small and disconnected patches throughout the open space (often referred to as "scattered sprawl" or "leapfrogging"). Therefore it is not only the quantity of land converted to urban uses that needs to be considered, but also the spatial patterns and their flow-on effects on environmental qualities that urban planning and management need to take notice of.

Fortunately, improvements in the resolution and quality of digital land use and land cover data have opened up new possibilities for a spatially more refined modeling of urban form, including measures for development patterns. In the recent past, numerous methodological approaches to provide quantitative assessments of urban form and urban sprawl have been introduced [8, 41–45]; see Chin [46] for a brief overview. Table 1 lists prominent measures (indicators) of land consumption and urban sprawl along with their function (description) and sources in the literature.

Looking at recent urbanization trends, land consumption can take very different intensities and forms. In Europe, the annual growth of urban land is expected to range between a maximum of 2% in rapidly growing areas and nearly 0% in remote rural regions [55]. For the period from 1990 to 2000, Angel et al. [2, p 56] estimated that the annual increase in built-up areas in developing countries was around 3.6%, whereas it amounted to only 2.9% on average in industrialized countries. Among the world regions, East Asia, including the Pacific, and Southeast Asia have witnessed the most intensive land consumption with growth rates of 7.2% and 6.4%, respectively.

Other studies provide empirical evidence that the spreading of urban land uses clearly exceeds population growth, resulting in declining overall densities (see, e.g., [2, 50, 53, 55–57]). In Germany, for example, per-capita land use for housing, transport, industrial, and commercial as well as recreational needs increased from 350 m in 1950 to more than 500 m in 1999 [58]. At the same time, in metropolitan areas urban density gradients have significantly flattened over time. It is worth mentioning that urban systems both in developed and developing countries have witnessed this process of decreasing densities, although it was more intense in the developed world [2]. Urban densities decreased between 1990 and 2000 worldwide, in East Asia by as much as 4.9% per annum and in Europe by a relatively moderate 1.9%.

The change of spatial configurations of urbanized areas that results from the shift of private households and firms from central locations to suburban and exurban areas is another highly visible characteristic of land consumption. Over time, metropolitan areas have changed their urban form from a highly concentrated compact structure to a rather dispersed or polycentric pattern [22, 59–63]. The deconcentration of urban systems ("suburbanization") has come along with a change of micro-patterns of urban form, often addressed with terms like "leapfrogging" or "ribbon" development. In this sense, land consumption has contributed to the large-scale transformation of urban

Landscape Planning for Minimizing Land Consumption. Table 1 Frequently proposed land consumption and urban sprawl measures

Indicator	Description	Sources
Size or share of urban land	Size of urban land (km^2 or sqm); percentage of urban land (%)	[2, 8, 42, 45, 47]
New land consumption	Converted urban land (in hectares or acres)	[9, 45]
Urban density	Number of people, jobs, or housing units per hectare of urban land (gross or net)	[2, 41, 45, 46, 48–50]
Change in urban density	Change of urban density between two base years (percentage)	[2, 19, 45, 51]
Density gradient	Regression of density against distance by ordinary least-squares (OLS) means	[41, 44]
Land use mix/land use separation	Degree to which different urban land uses exist in close distance to each other (measured with indices like the Shannon Diversity Index)	[42, 44, 46, 49, 52]
Continuity/dispersion/ fragmentation/complexity	The degree to which developable land is built up continuously; the degree of irregularity of built-up patches (measured with certain indices such as the patch density or more complex statistical measures of spatial regularity)	[8, 37, 42, 45, 46]
Concentration/ decentralization	Degree to which urban development is located near to the CBD (e.g., measured with the percentage of population and employment within concentric rings around the CBD or the median person's/worker's distance in distance units from CBD)	[37, 42, 44, 50, 53, 54]

systems from a compact urban form to an irregular, discontinuous, and dispersed urban land use pattern [31, 41, 42, 52]. Table 2 presents some characteristic "real world" examples for the spatial manifestation of "contiguous," "ribbon," or "leapfrogging" urban growth.

Drivers of Land Consumption

What factors account for the phenomenon of land consumption in general? What explains regional disparities in the rates at which land consumption occurs, and why do the patterns of land use conversions differ significantly between countries and even regions (e.g., [37])? Furthermore, why does land consumption often continue under conditions of stagnation or even decline [64]?

First of all, it has to be said that an explanatory model of land consumption cannot be deduced from a grand theory of urban growth or urban development simply because such a theory does not exist. However, social sciences and economics have offered theories that help to identify important drivers of land-consuming human activities. In particular, neoclassical economic theory provides a closed framework for the explanation of urban growth. It argues that location decisions of private households and firms reflect the aim to get the maximum utility out of matching space needs, location preferences, and financial budget constraints. Given an unregulated land market, land rents near the urban core are highest because transportation costs are lowest and accessibility of urban services is therefore best. It is the sum of all costs within the income elasticities for land and transportation that determines location choice. High-income groups (with more land-demanding aspirations) may prefer to live in a larger distance to the city center where large building lots are available, whereas low-income households will choose a location near the urban core with lower transportation costs. Based on these primary considerations, the monocentric model of urban spatial structure explains the spatial expansion of cities and density gradients with just a few variables, namely, the demand for new housing and commercial land,

Landscape Planning for Minimizing Land Consumption. Table 2 Types of urban sprawl (*grey colors* existing urban area 1990, *red colors* expansion 1990–2006; data sources: CORINE Land Cover 1990, 2000, and 2006, OpenStreetMap)

Types of urban sprawl	Examples
"Contiguous" or "continuous" development • New urban area is located adjacent to existing urban areas, expanding ring-wise around the central city • Structure: compact and "contiguous," possibly interrupted by topographic features • Land use: mono-functional or mixed, with residential and commercial use around subcenters, industrial along radial transport routes • Impact: flattened density gradient from the inner city to the city edge, well suited for mass transit systems, poor open space provision for inner-city dwellers	"Ribbon" development • New urban area is located near major transport network facilities (motorway on-ramps, public transport stations) • Structure: the resulting settlement patterns resemble strips or "ribbons" • Land use: often mono-functional residential areas preferred by commuters, extensive industrial (warehousing) or commercial use (shopping malls) • Impact: habitat fragmentation, inefficient in terms of urban service provision	"Leapfrogging" development • New urban area is located in isolated patches far from existing urban areas • Structure: dispersed and disconnected urban structures, surrounded by open space • Land use: mostly mono-functional industrial, commercial, or residential areas • Impact: relies on new infrastructure, inefficient to service with public transport and network infrastructure, fragmentation of open space; availability of nearby open space	
rising incomes, innovations of intra-urban transportation systems, and decreasing transportation costs [65–68]. In this sense, the growing physical footprint of cities and their declining density is the combined effect of a growing population, rising affluence, and enhanced individual mobility due to the increasing affordability of the private motor car.

Critics of the neoclassical monocentric urban model ("Alonso–Muth–Mills model") claim that many other factors than land prices and commuting costs affect location decisions [35]. Examples are the quality of urban services, specific priorities, and demands of different social groups in terms of urban and environmental amenities, or the desire to live in a socially homogeneous neighborhood. The Tiebout Local Public Finance Model [69] suggests that people decide to locate in a particular jurisdiction based on their preferences and taste for local amenities. Tiebout describes factors that "pull" people out of the central areas of metropolitan regions because of attractive characteristics of suburban communities (e.g., good service levels or lower taxes) and others that "push" people out of central areas as a result of central city problems such as crime or poor environmental quality and services.

The disagreement with the Alonso–Muth–Mills model is also fuelled by the empirical emergence of polycentric urban configurations [70–72]. The outward movement of jobs is regarded as a key factor explaining this trend. Suburban and exurban industrialization, beginning in the 1950s and 1960s, have made rural areas attractive to workers as new places to live in. In contrast to the fundamental assumption in the neoclassical city model that employment concentrates in the central business districts (and gradually decreases with increasing distance to the urban core), modern agglomerations in developed countries are characterized by their multinodal settlement system with a complex pattern of primary and secondary centers.

Next to economic theories, technical and social sciences aim to explain urban growth and the change of urban form [73]. Technical viewpoints focus on the role of transport innovations in order to explain the spatial diffusion of urban land uses. They associate the compactness of the preindustrial city with the fact that most trips had to be made on foot or similarly slow modes of transportation. This constraint disappeared with the availability of faster mass transportation technologies and the private automobile [74]. Following this logic, the physical growth of cities became a function of transport technology. Nelson [21] points out that other improvements in technology such as the personal computer, cellular phones, or the Internet may have encouraged the spatial decentralization of people and firms further, setting out the conditions for more land-intensive forms of urbanization.

On the one hand, economic, social, and technical theories help to explain the intensity of urban deconcentration and the associated rate of land consumption. On the other hand, they fall short of explaining the spatial patterns of urban land development. The reasons are manifold: neoclassical theory assumes that an unregulated market exists without any regulating land use policies (e.g., land use zoning) and that biophysical factors unfavorable for urban land use can be ignored. However, it is evident that these factors of urban development need to be taken into account to understand how actual land consumption patterns result from a complex interaction between various social, demographic, economic, and environmental processes. As a consequence, spatially explicit land use models have been developed that not only explain *at what rates* land use change occurs in a given period of time, but also address the question *where* land consumption will take place, that is, the likely location of change [5, 75].

For this purpose, Poelmans and van Rompaey [5] distinguish five groups of explanatory variables that are frequently used in models of land consumption:

- Biophysical factors may have an impact on the suitability of land tracts for the construction of buildings or infrastructure facilities. For example, factors such as slope or environmental hazards strongly influence the cost of development. Therefore, biophysical factors can explain why certain areas are excluded from development.
- Social factors put emphasis on location preferences of households (or household types). Examples are the income level or ethnic composition of nearby neighborhoods and the availability of public green spaces. These factors may encourage or discourage the choice of a development site.
- Economic factors refer to accessibility features as proxy values for market access. Frequently used measures are the distance to urban centers or main roads and the availability of public transport services in a walkable distance. Undeveloped properties with good accessibility are more probable to become urbanized in the future.
- Neighborhood interactions refer to an observed spatial autocorrelation between new developments and existing urbanized areas. In contrast, some potentially conflicting land uses (e.g., residential and industrial development) are unlikely to be located directly next to each other.
- Spatial policies are relevant because of their influence on the location decisions of private households and firms. These policies can be labeled "negative planning" where they aim to protect current land uses (habitat conservation, prime farmland) or "positive planning" where they define the suitability of a piece of land for a specific use (i.e., where they explicitly designate sites for urban development) (see also Legally Binding Land Use Planning).

Clearly, these determinants of land consumption encourage or constrain urban development with a certain spatial logic. Some of them may explain the total pressure on the land within a region or even

a nation state, but are hardly suited to identify the local hot spots of development. Examples are housing policies or mortgage schemes that support private homeownership. Other determinants can explain why certain plots of land were developed – for example, moderate land prices or above-average accessibility – while failing to explain the aggregated regional growth rate of urbanized land. Table 3 presents a set of relevant variables with their estimated explanatory capacity.

Recent studies [76, 77] have found that supply-driven factors of land consumption generally carry higher weights than the demand side. They suggest that land consumption is not only the result of demand driven by demographic and economic growth pressures or social preferences, but is also fuelled and facilitated by policies at national as well as local scales [78, 79]. For instance, the political agenda of local decision-makers in stagnating or economically declining areas often emphasizes the importance of cheap land for residential or commercial uses as a means to attract people and enterprise and thus to generate income tax. This can explain why some regions and municipalities without demographic or economic demand pressure show significant land consumption rates [80, 81]. Government policies like the commuter tax allowance in Germany, the financing of highway infrastructure in the USA, or subsidies for the development of industrial or retail development by the European Union are likely to support this effect [82].

Some scholars present evidence that the institutional fragmentation of local authorities could be another important factor explaining the rate and pattern of land consumption. According to this position, a decentralized land use governance with numerous local governments controlling urban land use is likely to promote urban sprawl as it increases the number of jurisdictions seeking for extra-budgetary revenue through land conversion to urban uses [48, 77, 83]. The size of local government units is also important in other ways – the bigger they are the less likely to be reliant on one particular investor or project, and less vulnerable to the influence of individual land owners with regard to planning policies and decisions. Furthermore, smaller communities are more likely to permit exclusionary zoning policies where local governments intend to exclude low-income groups from their

Landscape Planning for Minimizing Land Consumption. Table 3 Explanatory variables used in land consumption model applications (*dark grey* strong explanation, *pale grey* moderate explanation, *white* not relevant)

Factor	Examples	Explanation of rate of land consumption	Explanation of location of land consumption
Biophysical	Slope		
	Hazardous land		
Economic	Economic growth		
	Land prices		
	Distance to urban centers		
	Distance to the main road		
	Fiscal motives to convert land into urban use		
Demographic/ social	Population growth		
	Income growth and changes in lifestyles		
	Motorization		
	Social preferences for housing types and locations		
Spatial policies	Land use regulation (positive and negative planning)		
	Revitalization and renovation policies		
	Public funds for Greenfield development		

municipalities [79, 84]. These policies are driven by the suburban resident's desire to protect their housing investments and to maintain their social status [83].

Impacts of Land Consumption

Systematization As mentioned above, land consumption is a by-product of demographic and economic change. In a sense, land consumption is an indicator of prosperous development since it seems unrealistic to aim for strong economic growth without any land conversion. Improvements of housing supply, the introduction of modern transport systems, or the rise of economic productivity are mostly land-consuming activities. Downs [83] points out that urban sprawl produces some benefits for metropolitan citizens. Among others, he lists low-density lifestyles and the availability of private green space, an easy access to public open spaces in the countryside, a broad choice of places to work and live, relatively short commuting times for people who both live and work in suburban areas, and the ability of citizens to exercise strong influence on local governments.

At the same time, land consumption is responsible for many undesirable effects. In the scientific literature, numerous approaches to categorize these effects have been introduced (Table 4). They refer to causality, to spatial scales of impact phenomena, specific impact pathways, issues of concern (environmental, economic, or social issues), or the quality of effects as costs or benefits.

A first useful categorization distinguishes between single, that is, direct, and cumulative, that is, indirect, impacts. Conversion of forest to residential land, for example, is a direct effect causing the loss of vegetation or the sealing of natural surfaces. However, significant land use related environmental problems such as the modification of urban climate conditions ("urban heat island") or the increase in urban runoff often result from the cumulative effects of development activities rather than single projects. They build up over a period of time and usually have more than one cause. The individual effects from a single development activity may not be significant in terms of environmental harm (Table 5). However, when considered with other perturbations on the same environmental component (or system), they can become significant either through additive or interactive processes [85]; see also CEQ [86] and Parr [87].

Landscape Planning for Minimizing Land Consumption.
Table 4 Categorization of land consumption impacts

Dimension of categorization	Impact categories
Causality	Direct impacts
	Indirect or cumulative impacts
Spatial scale	Land unit-level impacts
	Context-level impacts
Issue of concern	Environmental impacts
	Economic impacts
	Social impacts
Impact pathway	Land surface related impacts
	Land use pattern related impacts
	Density related impacts
Quality	Impacts as costs
	Impacts as benefits

Closely related to the above-mentioned categorization, Nuissl et al. [92] differentiate a "land unit level" and a "context level" of land use impacts. Unit-level effects are the direct and immediate outcome of a change of land use on a particular plot of land. In contrast, context-level effects depend on the characteristics of the larger territory in which a land use change is taking place. The authors point out that these indirect impacts cannot be comprehended with a narrow spatial focus on the particular piece of land that is subject to a modification of land use or land cover. Examples are fragmentation effects of new roads or the attraction of motorized consumers by large-scale retail facilities.

Siedentop and Fina [45] distinguish three key dimensions of urban land use through which a broad range of land consumption impacts can be explained and modeled. These are land cover features (surface), the pattern of land use as the spatial configuration of urban and nonurban land patches, and the intensity of use (urban density). Table 6 summarizes well-documented impacts of land consumption and attributes them to certain impact pathways.

Landscape Planning for Minimizing Land Consumption. Table 5 A typology of cumulative effects with some examples of land consumption (Adapted from Cooper [85, p 3])

Type	Main characteristics	Examples
Time crowding	Frequent, repetitive, and simultaneous impacts on an environmental resource	Loss of prime farmland [88]
Space crowding	High spatial density of impacts on an environmental system	Emergence of an "urban heat island" caused by the spatial concentration of artificial surfaces and a lack of green space [89]
Cross-boundary movement	Impacts occur some distance away from source	Floods affecting downstream settlements caused – among other reasons – by increases in upstream urban runoff
Compounding/ synergistic effects	Effects resulting from multiple sources or impacts that may be different in nature from the individual impacts	Drawdown of groundwater levels due to increased imperviousness and increases in withdrawal of groundwater
Triggers and thresholds	Fundamental changes in system behavior or structure	Beyond a threshold of 15% imperviousness, urban stream quality becomes poor [90]
Nibbling	Incremental or decreasing effects	Gradual loss of greenbelt land through urban development [91]

Other studies categorize impacts with respect to certain issues of concern [125–127]. Often, a reference to environmental, economic, and social effects is made. Fig. 2 outlines some frequently addressed land consumption impacts and categorizes them with regard to the issue of concern and the spatial scales of their impact in an "urban sprawl" matrix.

Review of Important Impacts First of all, land consumption has sparked environmental concerns. Environmental effects of land consumption can be primarily explained with changes of land cover features that are inevitably related to urban development [99]. Natural or seminatural surfaces are converted to urban uses with a high share of artificial, impervious surfaces and complex effects on ecological systems [90, 100, 128]. Imperviousness is defined as the sum of roads, parking lots, sidewalks, rooftops, and other impermeable surfaces of the urban landscape [90, 129] (see Table 7 for an overview on the mean imperviousness of different land uses). In many studies, imperviousness has been used as an indicator to measure the impacts of land development on terrestrial and aquatic ecosystems. Imperviousness physically limits the infiltration of rainfall into the ground. Rainfall and snowmelt water disabled to infiltrate becomes surface runoff. Studies have shown that the urban runoff can be more than twice as high in urbanized than in rural areas with more natural land cover features [130]. Thus, soil sealing in highly urbanized areas is widely viewed as an important causative factor of flood risks [75]. Due to the fact that urban runoff water carries with it chemical pollutants (e.g., from automobile traffic or industrial land uses) imperviousness also contributes to the biochemical degradation of aquatic ecosystems. Based on many empirical studies, Moglen and Kim [128] estimate that when the rate of paved surfaces exceeds a threshold of 10–15% various indicators of biological stream quality decline markedly.

Moreover, the high percentage of imperviousness is also co-responsible for highly modified meso-climatic conditions in large urbanized areas ("urban heat island"). The spatial concentration of artificial materials with specific thermal characteristics creates local temperature anomalies leading to a higher average temperature in the dense urban fabric as compared to the urban periphery [89, 96, 97].

In addition to the magnitude of land conversion and imperviousness, the characteristics of the land that became urbanized within a specific period of time have to be taken into account (e.g., soil quality, habitat quality, vegetation, etc.). Of particular concern is the

Landscape Planning for Minimizing Land Consumption. Table 6 Land consumption impacts related to distinct impact pathways (Adapted from [45])

Impact pathway	Impacts of land consumption	Sources
Change of land cover (surface)	Continuous urbanization leads to a loss or degradation of valuable open space	[88, 93–95]
	The spatial concentration of pollutants is co-responsible for high air pollution	[51]
	The spatial concentration of artificial surfaces and a lack of green space is one causative factor for the urban heat island	[89, 96–99]
	The spatial concentration of built-up land has negative effects on the provision of green space	[99]
	Urban runoff from sealed surfaces negatively affects aquatic systems (water quality, biodiversity of systems)	[90, 100]
Changes of land use patterns	Dispersed and scattered settlement patterns hold responsible for high development costs (infrastructure)	[36, 101–103]
	Dispersed and scattered settlement patterns lead to higher travel distances and thus higher climate gas emissions	[62, 104–106]
	A discontinuous urban growth brings about higher levels of habitat fragmentation	[107, 108]
	The over-concentration of population and monocentric urban systems have a risk of higher levels of traffic congestion	[109, 110]
Change of urban densities	Low residential densities come along with a high level of automobile dependence	[111, 112]
	Low residential densities are usually associated with higher travel distances	[11, 49, 113–115]
	Low residential densities lead to less cost-efficient and effective public transit	[116–118]
	Low residential densities result in higher per-capita development costs (urban services)	[36, 103, 119]
	Low residential densities lead to higher energy use for housing (heating)	[120, 121]
	Low residential densities are co-responsible for negative health effects (due to physical activity levels)	[14, 122–124]

loss of prime agricultural land due to its importance for the long-term competitiveness and sustainability of agriculture [94]. The European Environment Agency [40, p 176] estimates that the "continent's best soils" are sealed due to the fact that most urban centers were built on fertile valley soils and around estuaries (see also [88, 133]). Hasse and Lathrop [94] present quantitative findings that prime farmland is more vulnerable to urbanization than farmland of lesser quality. Urban development in more and more fragmented agricultural landscapes can also be problematic for the production of food and fiber on the remaining farmland. For instance, conflicts between farmers and their residential neighbors "can arise over noise, chemical applications, and smells that are part of farming" [134, p 2].

In addition, dispersed and fragmented land use patterns are a crucial contributor to landscape fragmentation, which is characterized by a process of perforation, dissection, and isolation of habitat areas and natural or seminatural ecosystems [107]. Many scholars regard fragmentation as a major cause of the alarming loss of species all over the world [108, 135].

The (not purely monetary) costs for providing settlements with public services are commonly addressed in urban sprawl studies that focus on the economic effects of land consumption. In 1974, the "costs of sprawl" study [136] presented empirical evidence for

Landscape Planning for Minimizing Land Consumption. Figure 2
The impact matrix of land consumption

Landscape Planning for Minimizing Land Consumption. Table 7 Percentages of imperviousness for different categories of urban land use (Adapted from [92, 128, 131, 132])

Land use category	[131]	[92]	[132]	[128]
	Imperviousness (in percent)			
Residential	35–65	40–80	49	25–65
Mixed use	65	–	44	–
Public open spaces	–	–	15	–
Commercial and business	80	–	–	85
Institutional (public use)	–	–	59	50
Industrial	76–80	80–100	64	72
Transportation	58–63	80–100 (roads) 20–40 (rail)	–	75
Urban recreation (sport fields, public parks, private gardens)	4–8	–	–	–
Agriculture	0	–	2	–
Forest	–	–	2	–

a negative interdependency between the density of residential developments and the fiscal costs for providing basic urban services. The findings of this study triggered an intensive dispute not only with respect to the implications for urban development policies but also in terms of methodological uncertainties. A couple of subsequent studies confirmed the results of the 1974 work (see [36] with many references); others disputed the relevance of urban form variables on infrastructure costs [137, 138]. As a bottom line it can be said that it is

widely acknowledged today that low-density and dispersed urban developments are more cost-intensive than more compact development patterns (see also [101, 139–141]).

The impact of land consumption on motorized transport demand is probably the most frequently discussed issue in this field of research. Many scholars have shown that spatially dispersed urban areas accompanied by low densities contribute to larger travel distances [104, 114, 142, 143]. Based on a meta-analysis of the relevant literature, Ewing and Cervero [113] come to the conclusion that single variables of urban form have a relatively minor effect on motorized transport demand. However, the combined effect of several urban form variables on travel can be significant (see also [144]). Next to urban density, the accessibility of workplaces and other destinations, the mix of different land uses, the availability of public transit and urban design features are regarded as being influential on transport. Some critics dispute the causality between urban form and travel behavior, pointing to the possibility that private households self-select themselves to places that are in accordance with their preferences for particular transportation modes [145]. At the same time, studies that controlled for demographic, socioeconomic, and attitudinal variables (such as household income, family size, or age) presented contrasting results that identify a significant effect of urban form on transport [143, 146, 147]. Everything else being equal, households in peripheral low-density environments have longer travel distances and tend to travel by car more often than their inner-city counterparts.

Lastly, land consumption and urban sprawl have also been criticized for unintended social outcomes (e.g., [148]). The "spatial mismatch" debate, starting in the 1960s (see [149] and [150]), addressed the extent of limitations on residential choice for minority populations (especially Afro-Americans in the USA), combined with the intra-regional decentralization of employment. Proponents of the spatial mismatch hypothesis argue that the exclusion of low-income and nonwhite households from suburban communities together with the continuous spatial dispersal of jobs especially for low-skilled employees is responsible for the high rates of unemployment and low earnings of minority population members living in central cities. More recently, studies found evidence that low job accessibility in public transport catchments negatively affects the employment probability of social groups with a poor availability of cars [151].

The very recent debate concerning the effects of urban sprawl on public health – with a special focus on the relationship between urban form variables and physical activities with their corresponding health implications – demonstrates that the discussion on land consumption impacts is not closed (e.g., [14, 122, 124]). Moreover, the verification of alleged impact hypotheses with credible and disaggregated data and more robust methodological designs will help policy makers in justifying their potentially restrictive policies and measures.

The Means of Spatial Planning to Minimize Land Consumption

The Aim of Spatial Planning

The desire to control the dynamics of land consumption was one of the earliest motivations for spatial planning. However, while this desire used to be of minor importance in comparison to the goal of mitigating land use conflicts and safeguarding the most rational possible form of urban growth, it has become one of the major issues in land use policy only more recently (e.g., [152]). This issue is probably most disputed in the USA where public concern about sprawl grew heavily in the recent past [153], resulting in a strong anti-sprawl movement that meets strong opposition by more liberal academics and planners who emphasize the importance of individual choice and the free market (e.g., [28, 93, 154–156]). However, elsewhere, most notably in Western and Central Europe and Australia, this debate has also gained considerable momentum (e.g., [55, 157]).

As has been shown in the previous part of this contribution, at least in sustainability science and environmental politics it is now widely acknowledged that sprawl causes ecological damage, increases the need to travel, makes service provision more expensive, and has additional social and economic impacts. In 1999 the European Spatial Development Perspective recommended that "member States and regional authorities should pursue the concept of the 'compact city' (the city of short distances) in order to have better control over further expansion of the cities." "For this

purpose," the document continues "co-operation between the city and the surrounding countryside must be intensified and new forms of reconciling interests on a partnership basis must be found" [158 para 84]. This quotation gives a typical example of the risen sensitivity of the land consumption issue. However, while it implies a strong quest for the minimization of land consumption the quotation's latter part hints at the general aim of spatial planning to provide a legal and conceptual framework that facilitates societal progress and economic growth. Insofar, it is a major challenge for spatial planning to balance the minimization of land consumption with other planning goals that are associated with development. To achieve this complex mission, spatial planning has quite some strategies and instruments at hand, many of which are well proven.

A Taxonomy of Planning Instruments

Basically, spatial planning is about the organization and regulation of land uses. Thus, almost all strategic and instrumental approaches developed by spatial planning are potentially apt to contribute to the minimization of land consumption – provided they are used to pursue precisely this goal.

The debate on potential policy responses to land consumption is rather broad and a great variety of policy strategies has actually been put in place across different countries so as to mitigate land consumption. Therefore, first of all a broad categorization of planning instruments seems to be helpful, which groups these instruments according to the general approach they use. A common way to achieve such classification is to divide public policies into those concerned either with (a) regulation, (b) spending, taxation, and subsidy, or (c) advocacy. Considering the phenomenon of urban sprawl in the USA, Bengston et al. [159] employed a similar three-part classification of policy types for the control of urban sprawl. Adopting and slightly modifying their approach, we propose to differentiate the means of spatial planning to minimize land consumption according to where they are located on the continuum that expands between the poles of two basic planning principles:

- *Planning*, reflecting the "traditional" regulatory approach of spatial planning to set legally binding rules for the use of land via regulative plans, and
- *Market*, reflecting the "economic" approach of land use policy that employs "market-based instruments" that modify incentives in a way that leads actors to use the land in the intended manner. For instance, taxation schemes that put an additional cost on the development of land are surely among the most efficient means to minimize the total amount of urbanized land (e.g., [160]).

Between these two poles (somewhere "halfway") one can discern an array of instruments, which are primarily managerial by character and that basically aim at impacting on the decision-making processes that eventually lead to regulative or market-oriented land use policy measures. This group of instruments can be attributed to a third planning principle:

- *Management*, reflecting the "persuasive" approach that tries to change the behavior of land using actors, either by providing them with information on the consequences of their behavior or by involving them in a communicative process together with actors that want to restrict land consumption.

These planning principles are of course ideal types. In reality policy responses and planning instruments that address the problem of land consumption are frequently combinations of several instruments that entail different principles.

Table 8 illustrates the three general approaches land use policy can adopt to pursue its goals, including the goal of minimizing land consumption. However, only the regulative and the persuasive approach fall into the scope of spatial planning in a strict sense, while the modification of incentives is usually to be achieved in other policy fields, for instance taxation or social policy [161]. In the following sections, we shall therefore highlight those spatial planning instruments that can be attributed to either the regulative or the persuasive approach while economic instruments do not fall into the scope of this contribution. (However, this must not be misunderstood as a neglect of the latter's indisputable effectiveness.)

Regulation

Sector-Specific Planning and Comprehensive Land Use Planning In virtually all countries there are different fields of public policy, legislature, and planning

Landscape Planning for Minimizing Land Consumption. Table 8 A taxonomy of land use policy instruments

Governance principle	Planning approach	Examples of strategies and instruments
Planning	Regulation (law)	Land use planning, that is, Zoning, for example, [162, 163]
		Urban design planning (e.g., density controls), for example, [164, 165]
		Transit planning [166, 167] etc.
Management	Persuasion (information and communication)	Forums and roundtables, for example, [168, 169]
		Information campaigns, for example, [170, 171]
		Land use change assessment and forecasting tools, for example, [172, 173] etc.
Market	Modification of incentives	Development taxes, for example, [174, 175]
		Subsides (e.g., urban regeneration), for example, [176, 177]
		Tradable permit schemes, for example, [161, 178] etc.

that define regulations as to the use of land. Frequently we find a differentiation between comprehensive land use planning on the one hand – as a policy field that is focused on resolving land use conflicts and safeguarding the rational use of land – and sector-specific fields of policy making and planning on the other hand. They both produce legal framework conditions on how a piece of land may be used, but the latter formulate only particularistic demands for land (e.g., by defining the location of technical infrastructure, water reserve zones, or nature preservation areas) and leave the task of coordinating these demands and interests to land use planning.

In principle, all kinds of public planning that have an impact on land use can contribute to achieving minimal land consumption. For instance, when planning a new power plant or road infrastructure it is always possible and worthwhile to consider how much land needs to be developed to realize the project. The field of environmental policy is particularly important as to sector-specific plans with the potential to minimize land consumption. The plans that are elaborated within this policy field, frequently labeled landscape planning, are usually restricted to defining nonurban areas that must not be developed in the future and include more or less detailed rules on how these areas ought to be used. However, the kind of planning that is most relevant with regard to land consumption and its minimization is almost always comprehensive land use planning.

Land use planning is an integrative endeavor. Its major task is the coordination and balancing of the different demands for land, which are put forward by industry and commerce, by private households, or, not least, by sector-specific policies, that is, authorities who are in charge for the provision of the public with infrastructure and services. The ability of land use planning to achieve this integrative task, and thus to prevent the formulation of contradictory public demands or rules regarding the use of land, varies between different countries and largely depends on the functionality and powers of the respective system of land use planning (e.g., [179]). However, even in countries with well-established (and more or less sophisticated) systems of comprehensive land use planning it is often the case that sector-specific plans drawn up by different authorities prove inconsistent.

Legally Binding Land Use Planning Virtually everywhere, land use planning builds on the principle of *distinguishing different kinds of land use*. This principle, and the related practice, is usually named "zoning" in the English-speaking world. Zoning basically implies the delineation of particular (non-overlapping) pieces of land for which acceptable and unacceptable kinds of land use are defined more or less precisely. This may

include the definition of the kinds of activities that will be tolerable on a particular lot (such as open space, residential, commercial, etc.), or the regulation of building height, lot coverage, obligatory shares of green space, and similar characteristics, or some combination of these. The primary purpose of zoning is to segregate uses that are deemed incompatible.

The most basic distinction that can be made via zoning is between urban land, including land that is dedicated to future development, and nonurban land. Thus, the principal instrument of regulative land use planning to minimize land consumption consists in the preparation and legal enforcement of land use and development plans, which, by distinguishing between these two land types, confine urban development to a limited area and usually include regulations regarding the character and intensity of urban land use.

Depending on a country's planning legislation, land use planning either formulates rules only for the urban area of a respective administrative unit, including the demarcation of this area that may contain yet undeveloped greenfield land, or it defines land use classes (zones) for an entire administrative territory, which likewise includes the *classification of developable land*. Usually land use planning, like many other forms of public policy, operates at different spatial scales – thus yielding regulatory efforts at the local, regional, national, or even supranational level, which mainly differ as to both the precision and the enforceability of directives (see Fig. 3). This constitutes a *hierarchy of plans*, with the plans on the upper levels specifying the framework conditions the more detailed local plans must meet. At the same time, however, it is a basic principle of regulatory land use planning that the more general "upper-level" plans must not be at odds with existing local (zoning) plans. In the hierarchy of land use planning it is usually only the local plans that enforce the containment of urban development by categorizing the different pieces of land in a way that is legally binding for land owners and investors.

Beyond the fact that most countries in the world have a system of land use planning, which, in one way or other, yields compulsory plans that prescribe how the land may be used, this planning system can be organized rather differently. Accordingly, there is an immense diversity of forms that regulatory land use plans can take in terms of legal foundation, regulatory power, planning symbols, relation between planning tiers, or content – ranging from plans that endeavor

Landscape Planning for Minimizing Land Consumption. Figure 3
Stylized correlation between spatial level of planning and precision as well as enforceability of planning (Source: [180] modified)

to grasp and regulate the full complexity of spatial development on the one hand to elementary zoning plans that include only a few basic predictions as to the permissible developments on the other. In many European countries, for instance, local plans are framed by plans prepared at the regional level, that is, by medium tiers of administration. Where such an intermediate level of spatial planning is lacking there is sometimes a distinctive antagonism between the national state and the communes. In addition to the comprehensive land use plans, in some countries, such as the Netherlands or Germany, detailed urban design plans, specifying the physical form of future development, are prepared, especially for areas where some new development is to be expected. Other countries, such as the UK, rely mainly on the comprehensive land use plans and supplementary policy to control development, without the preparation of detailed urban design plans.

The use of compulsory land use planning can be based on two fundamentally different ideas. On the one hand, land use plans may be drawn up to provide for the legal preparation of future development by defining the location of developments or facilities that are to be realized in future – this can be called "positive planning." On the other hand, land use plans are frequently necessary to steer and curtail urban growth as well as to prevent certain unwelcome developments by excluding particular uses for particular lots – this can be called "negative planning ."

From its beginning in the nineteenth century modern land use planning was basically devised as a response to the rapid outward expansion of urban areas in the course of industrialization. Initially, planning thus adopted the "positive" rather than the "negative" approach in that it was not primarily concerned with the containment of urban development and land consumption but rather with its preparation and coordination. The idea that land is a finite resource emerged only much later, in recent times. It is also important to note that an effective system of land use planning that draws on the principle of zoning did not emerge simultaneously throughout the world. Rather, in contrast to those countries in western, northern, and central Europe where the idea of urban and town planning is well established and accepted, the current planning legislation and planning practice is a fairly recent phenomenon in many countries and, in even more countries, remains a highly contested area of policy and a somewhat toothless tiger.

The "negative" approach toward land use planning is clearly most effective when it comes to curtailing land consumption. At the same time, however, it usually means a considerable limitation of the landowners' discretionary scope regarding the use of their sites. It is therefore also particularly prone to provoke sharp resistance in particular at the local level where it is often in conflict with the interests of land owners, investors, and politicians (e.g., [181]). Hence, it is often recommendable to combine "negative" and "positive" planning regulations as the latter are usually less contested and can help making urban development less land consuming, too. An example for such combination is the permission to develop the land that is dedicated to urban uses at a considerable density (thereby lessening the pressure on greenfield land) while at the same time marking out extensive areas where building activities are strictly prohibited.

Regulatory Planning Instruments Beyond Legally Binding Land Use Planning In addition to its traditional instrument, compulsory land use plans, regulatory land use planning has a wide range of other means at hand that can be used to minimize land consumption either directly or indirectly. Four more recent examples of these additional regulatory means that have earned much attention in contemporary land use policy debates will be sketched out in the following. All of them are inspired by the normative ideas of environmental conservation and sustainability. While one of these instruments aims at influencing land use patterns directly, the other three do so in an indirect fashion.

1. In many countries planning legislation enables authorities to define *minimum lot sizes* or *minimum building density*. Both can be employed in order to prevent land consumption and urban sprawl (e.g., [182]). Minimum lot sizing is usually meant to preserve the rural character of the landscape by prescribing a size of plots that exceeds the usual size of residential sites by far. However, as an attempt to save the rural character of an area minimum lot sizing can easily fail, in particular in the vicinity of urban agglomerations, when affluent households

start acquiring the rural plots in order to build their house there (e.g., [183]). The definition of minimum building density, on the other hand, prescribes an economic use of urbanized plots that does not "waste" land. Involving a rather far-reaching and detailed regulation as to the usability of a certain plot of land, this instrument is most feasible in a spatial context where there already exists a high-density building structure and a political context where the power of spatial planning is generally accepted.

2. The proposal to coordinate the development of land through *tradable permit schemes* combines regulative land use planning with economic principles. In the USA, there are already several examples where this idea has been implemented [178, 184] but its intense discussion has also progressed in other countries such as Germany [185] or Italy [186]. Tradable permit schemes usually involve "a cap-and-trade" approach, which works as follows: State authorities define the maximum amount of developable land and then issue a limited number of permits that allow developing a certain share of this total amount of potentially new urban land. After their assignment to the actors, either authorities or private landowners, who – according to a respective country's legal system – are entitled to use them in order to develop land, these permits can be traded among the actors. Where the demand for building land exceeds the initial assignment of permits, additional allowances can be requested. In turn, actors with a weak demand for building land can put their surplus permits on offer. The basic hypothesis underlying the idea of tradable permit schemes is that the trading of allowances will eventually lead to the most efficient land use pattern (because local planning entities, developers, or property owners are deemed rational actors who compare the expected profitability of new building land to the market price for the required permits). However, the introduction of tradable permit schemes may also entail some difficulties. First of all, it is open to debate how the "cap" should be defined and how the initial allocation of permits should be organized (e.g., via auctioning or via a fair distribution between actors free of charge) without distorting the balance between actors and without jeopardizing institutional rights of local communes or property owners. From an environmental point of view one might also object that the system is only focused on aggregate land consumption figures and neglects the different environmental values and public good functions of different plots of land (e.g., [187, 188]). Yet again, a "cap-and-trade" scheme of tradable permits appears to be a promising instrument for minimizing land consumption as it provides the land-consuming actors with the highest possible decision autonomy, while at the same time assuring the achievement of the cap previously set.
3. In many countries, the rising awareness for environmental issues has led to the introduction of laws and schemes that provide for the *compensation of ecological infringements* by new developments. These are based on the simple principle to ask anyone who is responsible for an investment with negative environmental impact to invest into the improvement of ecological conditions elsewhere. In several countries a system of compensation has developed in recent years, including, among others, pools of plots where compensation measures may be implemented (by improving the ecological value of a respective plot) as well as detailed evaluation schemes that allow quantifying both the environmental impact of a particular development as well as the environmental benefit of compensation measures [189]. Compensation systems of this kind can help minimize land consumption in at least two respects. On the one hand, they simply make the development of new land more expensive, thereby impeding investments that foster land consumption. On the other hand, activities that mitigate previous land consumption can be acknowledged as compensation measures for new developments. Insofar it is for instance possible to oblige land developers to dismantle the water-bound surface of a brownfield plot or tear down empty premises.
4. The *definition of rules concerning the process of land use planning* can be an important control ensuring the efficient use of existing or planned urban areas and infrastructure, avoiding unnecessary land consumption. The obligation to check public plans for their eco-friendliness, including their impact in terms of land consumption, which is required by

a directive of the European Union (SEA Directive 2001/42/EC) since 2004 is a good example. The SEA procedures obligate land use planners and decision-makers to systematically evaluate the likely effects of a plan on the environment and to propose reasonable alternatives of the proposed plan or program. Therefore, the SEA can stimulate planners to look for less land-consuming ways to reach their goals. Another example is the "sequential test" in British land use planning. It requires local authorities to seek suitable brownfield areas first before preparing greenfield land. In the beginning this the "sequential test " only applied to new retail or leisure development [190], but more recently the concept has been extended to planning for residential development, thereby giving priority to reusing previously developed land within urban areas, bringing empty homes back into use and converting existing buildings in preference to the development of greenfield sites. This strategy is particularly relevant with respect to those regions where land consumption occurs in combination with decline (see the contribution by Haase in this volume).

Persuasion – Indicative and Informal Means of Land Use Planning

Besides the "hard" instruments of regulatory land use planning spatial planning has a wide array of "soft" instruments at its disposal. Even though it is the defining characteristic of these instruments that they do not involve the definition of legally binding rules for the use of land, they can nevertheless be very effective when it comes to minimizing land consumption. They include rather different tools such as nonbinding development and actions plans [191] (more or less sophisticated concepts for the organization of), round-table discussions, workshops, and public forums (e.g., [192]); GIS-based decision support systems (e.g., [193]); or initiatives to promote an urban rather than a suburban lifestyle [170]. Generally speaking, these "persuasive" planning instruments attempt to create a commitment to a common goal (i.e., to the goal of minimizing land consumption) and to find cooperative solutions for problems arising from conflicting demands on land use (whereas the regulatory instruments seek to solve these problems by exertion). Reflecting the experience that traditional "blue-print-planning " that mainly draws on regulatory planning tools is often unable to achieve its goals – due to its inability to handle the complexity of societal production of urban space [194, 195] – "persuasive" instruments are broadly accepted today and advocated as an alternative means of progressing in spatial planning.

It hardly comes as a surprise that indicative and informal instruments of spatial planning work fairly well in situations that entail a win-win-structure – for instance, if the national government has decided to allocate a big infrastructure investment in a particular region and the municipalities in the region have to discuss and agree about the details of the project. On the other hand, if a "zero-sum-game" is to be played it is much more difficult to convince the officials in charge to engage in some kind of cooperative action. This becomes manifest, for example, with most attempts to persuade, or push, municipalities to transfer some of their formal competences in spatial planning to the regional level, for example, a new supra-local authority that is installed to organize land development in an urban agglomeration [196].

The provision of information for those actors whose decisions actually determine the pattern of spatial development is a very "soft" but also, at least sometimes, a very promising strategy of spatial planning . With regard to the public actors the monitoring of spatial development and land use change has long been discussed as a means to promote sustainable development (e.g., [197]). The focal point of this discussion is the assumption that an enhanced knowledge on the environmental and social drawbacks of land consumption may lead policy makers to the conclusion that they should call for more efficient forms of spatial development. Moreover, such knowledge can serve as an additional source of legitimacy for the efforts of public authorities (at the supra-local, i.e., regional or national, level) that strive for a containment of land consumption and urban sprawl. Accordingly, various kinds of planning information systems have been designed the main task of which is the continuous provision of information on land use change to decision-makers, and sometimes also the public (e.g., [38, 198]). In addition, there is a further group of instruments that not only aim at monitoring the process of

land use change but also the effectiveness and success of growth management policies altogether (e.g., 75, 199, 200).

Apart from providing decision support to professionals, the publication of data from land use monitoring systems also helps raising public awareness for land consumption and facilitates participation in the planning process. While much of the decision-making surrounding land use changes can be attributed to the calculation of economic costs and benefits by individual firms and households with little concern for wider socio-environmental matters, it is interesting to speculate on the extent to which behavior might be changed through "promoting a non-sprawl culture (...) through education and dissemination" and by "advertising and marketing techniques" [201, p 19], similar to previous campaigns, for example, in support of waste recovery or against smoking in public places.

Models and Paradigms of Urban Development

Whether or not the goal to minimize land consumption can be achieved is not only dependent on the availability of appropriate strategies and instruments to influence or regulate land use changes. Rather, a normative idea on the optimal spatial structure of urban areas that provides orientation in applying these instruments is likewise important. Spatial planning has developed a number of models and paradigms of urban development which, among others, make a strong claim for an economic use of land. As regards the minimization of land consumption, (1) the Green Belt and the Urban Growth Boundary, (2) the various leitmotifs of urban development that promote the compact, polycentric, and mixed-used city, (3) and the prioritization of urban regeneration are among the most important of these normative ideas. Although addressing the complexity of the urban system at rather different levels, these ideas can be seen as specific kinds of planning instruments in that they all entail concrete assertions on how the result of land use change, that is, spatial planning, should look like. They are planning instruments in their own right, but both of a more "substantial" (i.e., material) nature than the instruments discussed above (which are neutral in terms of content and can be used to pursue very different goals). To unfold their instrumental character in the planning process, however, models and paradigms of urban development usually need to be sustained by employing both regulative and persuasive instruments (i.e., the more "instrumental" planning instruments) to implement them.

1. The delineation of *Green Belts* or *Urban Growth Boundaries*, respectively, are among the most famous "tools" designed by spatial planning so as to provide a clear orientation about where to steer new development to and where to prevent urbanization (e.g., [202–204]). While both involve the idea to define a ring of open land that surrounds the urban area, the former notion usually implies a precisely defined line beyond which no building activity must take place whereas the latter is the more generic notion that is often used in nonbinding, regional plans and thus needs to be enforced by specific plans that prohibit development in the Green Belt areas. As long ago as 1944 Abercrombie's Plan for Greater London successfully employed the idea of a green ring that separates the metropolis from the surrounding landscapes – combined with the designation of a series of "new towns" as decentralized growth centers [205, 206]. In particular the concept of the Urban Growth Boundary is difficult to apply in densely populated regions where a sharp distinction between urban and rural areas is often hardly possible. In addition, there is a broad debate in the USA on whether the definition of a rigid boundary around a settlement is indeed the most effective means to curb urban sprawl and its associated negative impacts (e.g., [207]). Several scholars claim to have proven this assumption (e.g., [208]) whereas others doubt it (e.g., [209]). Likewise, Green Belt policies or Urban Growth Boundaries can prove unsuitable in a situation where informal housing is a frequent phenomenon [210]. In such a situation it is hardly possible to limit the outward expansion of the urban area, while, at the same time, it is important to involve the inhabitants of the proliferating informal areas in the planning process, rather than posing threats to their security of tenure by a desk-top zoning of land uses [211]. The implementation of Green Belts and Urban Growth Boundaries requires the decided use of compulsory

land use plans in the way of "negative" planning . It will only be successful if there is broad support for a policy that deprives land owners of the chance to develop their sites if this site is located beyond the imaginary line planners have conceived between the urban and open space [212]. Therefore, whether or not a Green Belt or an Urban Growth Boundary can be implemented in practice largely depends on the distribution of political powers between the main actors of urban development, and in particular on the power of regional planning to pursue its goals.

2. Spatial planning has ever since been strongly influenced by the predominant *leitmotifs and guiding stars* of the time regarding the optimal urban environment – in fact without its foundation in visionary ideas planning would be a somewhat uninspired, bland business. Today the chief guiding stars in urban planning promote, in one way or another, the economic use of land and thus the minimization of land consumption. This is particularly true of the ideal of the mixed use and compact city (e.g., [213]), which is at the heart of, for example, the New Urbanism campaign in the USA [214] as well as the discourse on the European City that has become influential in particular in Central Europe [215]. These guiding stars have developed over the last several decades as a reaction to the neglect of the particular qualities of "urban" environments that was characteristic of the postwar principles and trends of urban development [216]. Decentralized concentration is another leitmotif of spatial development that rather addresses the regional level of planning. It is based on the somewhat dialectic idea that, on the one hand, development (including the development of fresh land) should be promoted in less privileged, peripheral regions but, on the other hand, should be steered to selected locations in order to prevent an inefficient and unwelcome dispersion of development activities [217, 218]. Although the leitmotifs and guiding stars of urban planning are usually not primarily focused on land use issues but rather sketch out a more general idea of "the urban" (which is embedded in an even broader utopian idea of society), their clear intention to concentrate on urban development can mean considerable ideological support for a policy in favor of minimization of land consumption.
3. It is widely acknowledged that policies to minimize land consumption will only be successful if they go hand in hand with efforts to encourage *urban regeneration*, that is, the revalorization or reuse of land that has already been developed [219, 220]. Within the last around 50 years, in many countries a variety of strategies and instruments have emerged to promote urban regeneration. These include specific legislative measures that regulate urban renewal processes (e.g., [176]), urban regeneration schemes aiming to reestablish the attractiveness of inner urban areas (e.g., [221]), congestion charges in inner urban areas [222], or graduated density zoning [223]. These efforts help making the existing urban area as attractive as the newly developed areas as a place in which to invest, develop, produce, live, and work, from the perspectives of economic return, social satisfaction, and environmental quality [224]. If the endeavors to promote urban regeneration are successful they provide a powerful support for the minimization of land consumption; if they fail it will be hardly possible to (re-) direct the focus of investors and households away from suburban Greenfield land and to win them over for more compact development patterns.

Practical Challenges: Spatial Planning as a Governance Endeavor

There is no doubt that spatial planning in most countries in principle disposes of the means to minimize land consumption. Accordingly, we can find countless examples where decided planning efforts have contained land consumption (e.g., [20, 225]) as well as several studies that conducted a comparative evaluation of growth management policies in different regions and found them to have significant impact (e.g., [226–228]). On the other hand, some authors remain somewhat skeptical as to the effectiveness of growth management via spatial planning (e.g., [79, 229]) or even oppose the very idea of intervention in the dynamics of land use change (e.g., [155, 230]). When it comes to discussing whether the actual containment of land consumption has indeed mitigated the negative impacts attributed to urban sprawl,

opinions are even more split as can be seen from countless studies on the urban sprawl issue (see [219, 231, 232], to name but three examples). To give an example from the USA for this divergence of expert views: When comparing federal states with and without growth management programs, Nelson [21] and Kline [233] arrive at completely contrary conclusions as to the success of these programs.

However, the mixed opinions about the overall success of efforts to reduce land consumption by means of spatial planning are only one important aspect. It is likewise essential to account for the fact that the implementation of such efforts is by no means only dependent on whether planners or other experts expect them to be successful. Rather, spatial planning is the result of a political process (and not just a directive endeavor possibly led by public representatives who are highly conscious of environmental issues) [77]. In other words, the mere existence of powerful planning tools that can restrict land consumption does not guarantee their use. Frequently, the problem is not the availability of legal controls but their usage by different public agencies who by no means always regard the minimization of land consumption a top priority (e.g., [234]). Furthermore, minimizing land consumption is a common interest goal that has to be pursued mainly by state authorities (supported by environmental groups) against both other common interest goals (like increasing the number of jobs or the local tax base) as well as the individual interest of land owners and developers to use the land for their purposes (e.g., [235]). Thus, the question arises whether some provision can be made that spatial planning works in favor of a minimization of land consumption at all.

Due to the differences that exist between the planning systems of different countries – and also because of different legal and administrative cultures (e.g., [236]) – it would not be feasible to provide general recommendations as to how spatial planning systems can be instigated to minimize land consumption. Neither is it possible to formulate universally applicable assumptions as to the optimal strategy of land use policy and spatial planning, let alone the use of particular planning instruments. Rather, "anti-sprawl policies must be tailored for the particular patterns extant in the area at hand" [237]. However, it is possible to name a few aspects that should be taken into account wherever spatial planning is expected to help minimizing land consumption.

As we have seen, different state tiers usually have their own means of land use planning that they employ to pursue their specific goals. As a rule, it is at the local level where the opportunity to curtail land-consuming development is usually most, but the willingness to actually inhibit development least pronounced [238] – while we often find the reverse situation at the regional or national level. The task of minimizing land consumption is therefore a characteristic problem of multilevel-governance. This is particularly so where local authorities largely depend on their own tax bases (like in the USA or Germany) because this situation tempts them to use their power to dedicate the land to certain uses to attract tax payers or investments (e.g., [239]). Administrative fragmentation can further aggravate this situation as it increases the number of competitors trying to attract investments by offering fresh land (e.g., [240]; see also Drivers of Land Consumption). Overall, it is important to note that planning law provides local authorities with both the means to minimize or to promote land consumption – and they will often use it to promote growth rather than contain development.

As the containment of urban sprawl and the preservation of the landscape is often an important goal of supra-local land use policies, regional planning can play a key role in controlling land consumption. It can impose a set of aims and provide a framework for the operation of planning on lower government tiers. It can also organize a process in which different actors, including the region's local authorities, develop a joint idea on the future spatial structure and land use patterns of the region [241]. The commitment of local authorities and other actors to such idea will usually be the stronger the tighter they were integrated in the process of designing the common plan, beyond the usual consultations. Generally speaking, it is advisable to enact growth management policies at a spatial scale that is sufficiently large to rein in local parochialism ([31, 226]). With respect to the situation in the USA, Bengston et al. suggest that "with regard to vertical coordination (. . .) growth management is most effective within a statewide context, so that each level of government coordinates their plan with other governmental levels.

Horizontal coordination is needed to help avoid situations in which growth management policies in one jurisdiction undermine policies or create burdens in neighboring communities" [159].

However, it may well be the case that regional or state authorities are hardly inclined to enact a containment of land consumption because they too sometimes emphasize growth as a major aim of public policy. This situation is particularly likely to occur where the responsibility for regional planning lies with an association formed by the region's local authorities (as is the case in many federal states in Germany). Razin [242] has questioned the likelihood of land consumption being successfully controlled by "macro-scale regional plans" and planning regulations and argues in favor of changes to both local tax regimes and local government structures as a more effective approach.

It can be concluded that spatial planning alone will hardly suffice to minimize land consumption. Therefore it should be complemented by other means of public policy (e.g., [19]). In particular three aspects are worthwhile considering in this respect:

1. Firstly it is important to consider the potential land-consuming effects of all types of public policy, for instance, land readjustment policies (e.g., [243]), tax policies (e.g., [244]), subsidies (e.g., [245]), and, in particular, public investments in transportation infrastructures(highways, public transport, parking lots, etc.). There is considerable evidence that the latter stimulate urban sprawl [246, 247]. For instance, radial rapid transit systems in urban agglomerations, together with park and ride facilities, do not only define the potential nodes of compact development but usually also enhance the attractiveness of suburban locations (as compared to the inner city) by improving their accessibility and making the journey from suburbia to the urban core more convenient.
2. Secondly, economic policy instruments can significantly support spatial planning in its attempt to minimize land consumption [187]. These instruments can be used to profoundly alter the framework conditions for individual action and thus to make "land-consuming activities" much less attractive [248]. In this vein, a number of suggestions are available on how fiscal incentives may be introduced that work in favor of the minimization of land consumption [175]. Likewise, the aforementioned tradable permit schemes provide an example of how regulatory land use planning may be combined with economic instruments.
3. Thirdly, it seems obvious that a policy that really aims at minimizing land consumption has to be much more decisive in supporting inner-city (in comparison to suburban) developments than is the case today [249, 250]. In particular, this could mean that subsidies and tax-depreciations for greenfield developments must be abolished, or even allowed only for inner urban projects.

Future Directions

It is widely accepted that extensive land consumption leads to the unwelcome loss of open land and natural resources, causes ecological damage, generates unnecessary traffic, wastes energy, leads to atmospheric pollution, and imposes economic costs on local authorities as inner urban services and amenities lie underused – let alone the potential social effects of urban sprawl such as the exacerbation of spatial social segregation and the exclusion of non-car-owning households from a good deal of work and leisure facilities. The minimization of land consumption is therefore usually an important goal of land use policy. Spatial planning is the major means to pursue and achieve this goal although the heydays of spatial planning and regulation of land use have been in the 1960s and 1970s and are long over. Looking to the future, however, we may expect spatial planning to increase in importance again, mainly because of the risen concern about environmental issues and the introduction in many countries of stronger requirements for considering the environmental impact of development.

Overall, there exists a wide range of strategies and instruments that can be employed by spatial planning to bring land consumption under control. The strategies and instruments that are in use in different countries share many basic features – however different they may be in detail, in particular due to the peculiarities of the respective legal system. Against this background, it will be a crucial task for future applied research on land use and spatial planning to continue with the ongoing

efforts to evaluate the various instruments and strategies that aim at minimizing land consumption (which were mentioned above in particular in Practical Challenges: Spatial Planning as a Governance Endeavor). Apart from this general assertion, regarding the utilization of planning strategies and instruments a series of relevant issues and research questions can be defined that deserve the attention of both academia and practitioners:

1. It appears crucial to embed any attempt to minimize land consumption by spatial planning in a strategy that at the same time eliminates existing incentives for land-consuming development. It is therefore important to identify and then tackle such incentives in, for instance, tax policies or policies for structural development.
2. Given the variety of regulative planning instruments it would be worthwhile to scrutinize the feasibility and effectiveness of possible combinations of different instruments. In this vein, the thorough evaluation of management and containment policies that already exist in different states or regions will be particularly instructive.
3. Since the minimization of land consumption is largely dependent on the political will to achieve this task (which is often lacking), the provision of powerful tools to monitor land use changes and to assess their various impacts is essential. Therefore, current efforts in land use science to develop such tools that are easy to handle and allow establishing the overall effect of land-consuming activities can provide a major contribution to the minimization of land consumption.
4. The ongoing attempts to seek for scientifically sound arguments in favor of compact urban development can supply the efforts to minimize land consumption with weighty arguments.

Finally, it is always important to acknowledge the particular context in which the minimization of land consumption is to be achieved. The existence of a similar set of regulatory means in different countries, for instance, is by no means tantamount to their practical relevance also being similar in these contexts. Likewise, the perception of urban form and density patterns or the reaction of people to anti-sprawl campaigns may vary considerably from place to place. Against this background, it is virtually impossible to transfer planning strategies and instruments by means of which authorities try to minimize land consumption from one legal and cultural context to another without further ado. Therefore, it remains a major research task to keep an eye on practical experiences regarding the applicability of planning strategies and instruments in different contexts as this will provide a basis for their adaption to the context in which they are to be utilized. Without such effort to allow for the particularity of different contexts it seems hardly possible to control, manage, and steer the development of fresh land to the most acceptable locations and to minimize land consumption, and thus to increase the sustainability of land use patterns.

Acknowledgment

We would like to thank Stefan Fina for his valuable guidance and stimulating discussions.

Glossary

Catchment (or river basin) The drainage area of a stream, river, or lake. It has a common outlet for its surface runoff.

Ecosystem An arbitrary ensemble of macroscopic matter that captures, stores, and uses energy to circulate and rearrange matter within the system.

Evaporation (of water) (1) The emission of water vapor by a free surface at a temperature below the boiling point. (2) The amount of water evaporated.

Interception loss Rainfall evaporated from canopy and litter.

Landscape The traits, patterns, and structure of a specific geographic area, including its biological composition, its physical environment, and its anthropogenic or social patterns. An area where interacting ecosystems are grouped and repeated in similar form.

Landscape ecology The science of studying and improving the relationship between spatial pattern and ecological processes on a multitude of landscape scales and organizational levels. Landscape

ecology is highly interdisciplinary and integrates biophysical and analytical approaches with humanistic and holistic perspectives across natural and social sciences.

Landscape structure, function, and pattern structure Is determined by the composition, the configuration, and the proportion of different patches across the landscape, while *function* refers to how each element in the landscape interacts based on its life-cycle events. *Pattern* is the term for the contents and internal order of a heterogeneous area of land.

Landscape planning The aspect of the land use planning process that deals with physical, biological, esthetic, cultural, and historical values and with the relationships and planning between these values, land uses, and the environment.

Landscape water balance Inventory of water based on the principle that during a certain time interval, the total water gain to a given catchment area or body of water must equal the total water loss plus the net change in storage in the catchment or body of water. In hydrology, a water balance equation can be used to describe the flow of water *in* and *out* of a system. A *system* can be one of several hydrological domains, such as a column of soil or a drainage basin.

Scale A definition applied to the time, space, and mass component of any quantity is that scale denotes the resolution within a range of a measured quantity. This definition encompasses two important, interacting facets of scale: resolution and range. Resolution or "grain" refers to the finest distinction that can be made in an observation set, while range or "extent" refers to the span of all entities that can be detected in the data.

Transpiration Process by which water from vegetation is transferred into the atmosphere in the form of vapor.

Definition of the Subject and Its Importance

Extreme events such as floods, droughts, as well as water scarcity and poor water quality have been increasing globally during recent decades. Global change phenomena, increasing population density in some parts of the world, as well as multiple land use of landscapes such as agricultural management, urbanization, and industrialization are some of the main reasons for these problems. Both the mentioned reasons as well as the resulting environmental consequences, represent some of the world's most pressing problems that occur on different scales – from the field to the region or even globally. In recent decades, integrated river basin and environmental management – including landscape planning – have been introduced as a potential but challenging instrument to tackle these complex transdisciplinary problems around the world. However, several problems still exist before an effective integrated planning and management can be realized. This section introduces these problems and presents contributions to the solution for some of these (methodological but also environmental) problems. In the following, the existing problems and needs of the handled topics are briefly argued, and numerous studies on the solutions to these problems are shortly illustrated. In the sense of an integrated methodology, promising developments of decision-support systems are presented as one future direction to support sustainable land use planning and water resources management. Finally, criteria for sustainable water planning are presented.

Introduction

"Water is life. It nourishes our ecosystems, powers our industry, grows our food, and makes life itself possible" [1]. This statement emphasizes the importance of water for humans and nature. The human factor "land use" affects the interactions between the components of a landscape structure in different manners and intensities. Landscape pattern or structures consist of water, soil, geomorphology, vegetation, etc. Water-carried fluxes of matter (nutrients, sediments) and energy play an important role for the landscape balance. All components of the landscape structure are interrelated by these fluxes. Hence, society needs a way to handle a landscape as a whole, so that the human manipulative capabilities do not have too much head start over our knowledge about the impacts of these manipulations [2].

However, extent and rate of effectuate changes in landscapes still exceeds, to a high degree, the scientific capability to reliably predict long-term impacts of technological developments on natural cycles and

processes. Human impact not only on landscape pattern, water balance, material fluxes, habitats for plants and animals, but also on socioeconomic situations has in fact reached a degree that may lead to irreversible changes and put at risk the natural systems essential for life support. Thus, landscape ecology and other environmental sciences have to develop suitable and improved methods to assess the impacts of anthropogenic changes in landscapes and to develop a conceptual base for sustainable land use.

Land use is the parameter by which society controls the landscape water balance [3]. It controls not only parameters such as evaporation, surface runoff, or groundwater recharge in catchments, but also soil erosion and water quality. Figure 1 shows the complex interrelationships within the water cycle. The water cycle links evaporation from the sea, atmospheric water vapor flow, the moistening of continental landscapes, the recharge of aquifers and rivers, and the river discharge back to the sea. The human physical and chemical interventions (including land use in all its forms) influence the atmosphere, the landscape, and the aquifers and rivers [1]. Hence, the investigation of the effect of land use change and land use patterns on the water resources provides information for the development of sustainable land use concepts and integrated environmental and river basin management as demanded by landscape programs or political directives. Examples for such directives are the Clean Water Act [4] in the USA or the European Water Framework Directive (WFD; [5]) in Europe. Due to the oftentimes insufficient water availability or poor water quality of the streams these environmental programs were implemented to achieve good ecological and chemical conditions of water quality of groundwater and surface water bodies.

In addition to these directives, land use plans (for different scales such as communities, counties, states, or even nations) based on ecological principles (landscape ecological plans) are finding increasing application, especially in continental Europe and the USA [6]. This reflects a growing maturity in landscape ecology, enabling it not only to inform theory, but also offer solutions to "real-world" planning problems. In countries with a long history of industrialization, visual distinctiveness and biodiversity have been severely eroded by a combination of habitat removal and fragmentation, intensive farming and forestry, river engineering, transport corridor construction, and industrial pollution and dereliction. More subtle effects, associated with pollution and nutrient transfers by air and water, have also had significant impacts [6].

On the one hand, the spatial distribution of different land use types (settlements, forest, grassland, pasture, arable land) affects the water and nutrient cycle of a landscape, but on the other hand also the different types of land management (crops, tillage, etc.) are important factors that influence these cycles. Table 1

Landscape Planning for Sustainable Water Usage. Figure 1
The continuous water flow through the water cycle, linking sea evaporation, atmospheric vapor flow, moistening of continental landscapes, recharge of aquifers and rivers, and outflow to the ocean ([1], see also [7])

Landscape Planning for Sustainable Water Usage. Table 1 Percentage of soil evaporation, interception loss, and transpiration of different land uses and land cover on total evaporation [8]

	Soil evaporation	Interception loss	Transpiration
Forest	–	40%	60%
Pasture	15%	25%	60%
Arable land	30%	15%	55%
Bare fallow	100%	–	–

gives an impression on the percentage of soil evaporation, interception loss, and transpiration of different land uses and land cover on the total evaporation.

Sustainable land use and management needs a sound knowledge of these influences. Hence, there are numerous examples for studies described in literature where measurements and computer-aided hydrological models are applied successfully for the simulation of the influence of land use and management changes on potential groundwater recharge or streamflow. Mostly variants or scenarios are investigated that are based on assumptions of climatic change or of the influence of political decisions. When simulating water balances for large areas, only considerable land use changes result in noteworthy shifts of the simulated total runoff. Depending on the selected model type, database and regional site conditions of the study site, land use changes can affect the results (and also the further modeling) to varying degrees. The assumptions of land use changes can be made on the basis of plausibility considerations, or models can be applied [9]. Overviews of the prospects and limitations of eco-hydrological models for evaluation of land use options in mesoscale catchments are given by Fohrer et al. [10] and Hörmann et al. [11]. On the one hand, such influences of land use and management have to be reduced that have a negative impact on the water resources. On the other hand, land use and management can be used as instruments to realize sustainable landscape development. The complexity of these interrelationships on different scales makes its study extremely challenging. The examples presented in this chapter are mainly from the "developed" world, such as from Europe, the USA, or Australia. Despite existing problems, the presented examples in these regions are with no doubt "best cases" for landscape planning and sustainable water planning. However, especially in the developing regions with an increasing number of drought and flood events and water quality problems, there is an urgent need for integrated landscape and water management strategies [1]. This becomes even more important with regard to the enormous regional differences of water availability in the world (as presented Fig. 2). Figure 2 shows the global distribution of water availability at country level.

Processes and Planning on Different Scales

Land use affects the interactions between water, soil, geomorphology, vegetation, etc., on several scales in different manners and intensities. That means that both natural processes and environmental problems occur on different spatial and temporal scales, from the field to the region, and even globally [12–15]. Due to the long tradition in scale-specific research in landscape ecology, several methods are available for the investigation of landscape ecological structures and processes on, for instance, fields or farms (the microscale), where the processes have to be measured or mapped, as well as for the whole world, where for instance climate is simulated by using General Circulation Models (GCMs). Only a few studies deal with the optimization of the scale-specific applicability of these methods and models, especially for larger scales [16–18]. But most of the environmental changes and conflicts between land use, conservation, and resource management become obvious at the so-called landscape scale [19]. Special attention should be paid to the investigation of the landscape water balance – at least in temperate and humid zones, because water-carried fluxes of matter and energy play an important role for the landscape balance . All components of the landscape structure are interrelated by these fluxes. Therefore, special indicators and model applications have to be developed for landscape-scale investigations that allow assessments and forecasts about the impacts of land use changes on the landscape balance.

Several papers from different scientific disciplines deal with the hierarchical organization of nature [20]. An overview about hierarchical concepts in landscape ecology is given by Klijn [21]. These concepts are mainly focused to the hypothesis that each of the scale levels (micro-, meso-, and macroscale) is characterized by specific temporal and spatial ranges. As a consequence, each scale level needs data layers with suitable spatiotemporal resolution and specific investigation methods and provides specific knowledge [22]. The main topic here is the definition of a linkage of the different landscape scales. The main hypothesis of the hierarchical approach suggested by Steinhardt and Volk [17, 23] is that the basic components for vertical and horizontal material and energy fluxes – morphology, soil, hydrology, land use and land management, and

Landscape Planning for Sustainable Water Usage. Figure 2
Availability of freshwater through average river flows and groundwater recharge, in cubic meters per capita per year, at the national level in the year 2000. The graphic highlights the countries with the least freshwater resources (Egypt and the United Arab Emirates) and those with the most (Suriname and Iceland)

climate – are similar over all scale levels. It is only the importance of the factors of these components that changes for each scale [24]. To give an example for morphology and erosion: On the local scale, surface roughness is one of the main factors that will affect erosion disposition, whereas for larger scales (up to river catchments) the factors slope inclination, slope length, slope exposition up to the shapes of streamlet, -net, -order, and direction of flow are responsible for erosion processes.

According to the hierarchical organization of nature spatial planning and forest, biodiversity, agriculture, and water management are also organized hierarchically (Fig. 3, Table 2). In Germany, regional management plans are instruments within the spatial planning system used to set guidelines for landscape development on the regional scale. Priority areas for "landscape functions " are designated at the community level. But there are only few applications of landscape ecological information – especially about the regulation capacity – that are included, and the realization of sustainable development requires the recognition of all landscape functions. Therefore, useful indicators and parameters have to be derived for analyzing and optimizing the regulation and production functions of the existing landscape types for the concerned scales [25, 26].

Effects of Land Use Pattern on the Hydrological Cycle

Measurements

The impact of land use and land cover change on the hydrological cycle can be quantified by using different

Landscape Planning for Sustainable Water Usage. Figure 3
Scales and planning units in forestry, biodiversity, and agricultural and water management

Landscape Planning for Sustainable Water Usage. Table 2 Hierarchies in landscape and spatial planning in Germany (after [27])

Scale level	Planning level	Spatial planning	Landscape planning
Macroscale	Country	Spatial development policy	–
Mesoscale	Federal scale Region	*Raumordnungsplan* *Regionalplan (= regional planning program)*	*Landschaftprogramm* *Landschaftsrahmenplan (= landscape program, landscape framework plan)*
Microscale	Municipality (town, village) Parts of municipalities	*Flächennutzungsplan* *Bebauungsplan (= land development plan, zoning plan)*	*Landschaftsplan* *Grünordnungsplan (= landscape plan, green structures plan)*

methods – depending on topic and scale one is interested in. One way to quantify the impact of vegetation cover change on the hydrologic cycle is paired watershed experiments [28, 29]. In a paired catchment experiment, land use is held constant on the control catchment and changed on the treatment catchment. Differences in hydrologic response with respect to annual runoff, flood, and low flow response and water quality can then be compared for catchments experiencing the same weather patterns [30]. Hibbert [31] gives a summary of 39 catchment experiments. He concluded that the reduction of forest cover increases water yield and in contrast the establishment of forest cover on sparsely vegetated land decreases water yield. The response to treatment was highly variable and thus for most parts unpredictable. Bosch and Hewlett [32] added another 55 catchment experiments to this review and sorted them by mean annual precipitation, vegetation type, and country. They confirmed the first two statements of Hibbert [31] and concluded that "coniferous forest, deciduous hardwood, bush and grass cover have (in that order) a decreasing influence on water yield of the source areas in which these covers are manipulated." Coniferous forest causes around 40 mm change in annual water yield per 10% change in forest cover. Deciduous hardwoods are associated with

a 25 mm change in yield per 10% cover change, while bush and grassland generate around 10 mm of difference. In their data set, forest cover changes of less than 20% could not be detected by measuring stream flow. Stream flow response to deforestation or afforestation depends both on the region's mean annual precipitation and on the precipitation for the year under treatment. Yield changes are greatest in high-rainfall areas. In low-rainfall areas the effect is less pronounced but more persistent due to slow vegetation regrowth. Decreases in water yield following afforestation seem to be proportional to the growing rate of the stand, while gains in water yields after clearfelling diminish in proportion to the rate of recovery of the vegetation. Smith and Scott [33] found that the dry season flow from forested catchments was lower than from comparable non-forested catchments in South Africa. Burch et al. [34] and Peck and Williamson [35] address the hydrological aspects of forest replacement by annual crops or pasture. The latter focused on the effect of deforestation on groundwater in five Australian paired catchments (0.8–3.5 km). Clearing increased the average recharge rate documented by piezometer hydrographs. Potentiometric heads within the forest and up to 50 m down-gradient from areas that were cleared have responded to clearing after a delay of 2 or 3 years. This delay was consistent with the very low transmissivity of the aquifer under observation. Burch et al. [34] compared two experimental catchments; one vegetated by natural eucalypt forest (5.0 ha) and the other completely clear-cut and maintained in grassland (7.8 ha) for over 80 years. The grassland catchment generated high-peak storm flows and large discharge volumes irrespective of antecedent soil water content, whereas the forested catchment gave little runoff provided the antecedent soil water content was below 60% of the available storage capacity. In the case of woodland establishment a substantial reduction of runoff was reported by Williams et al. [36].

In single-catchment experiments, the effect of land use change is measured by comparing measurements before and after the change occurred. Thus it is more difficult to separate the effect of land use change from the effects of different weather patterns before and after the change. It is a common knowledge that discharge from forest, urban, and agricultural catchments is different, but the experimental quantification is still not easy. A simple, but radical solution is the clear-cut or afforestation of entire catchments [37–39]. An overview of conversion studies from and to forest is given by Whitehead and Robinson [40]. An overview of paired catchment studies, where only a part or a subcatchment is changed, was published by Best et al. [28]. Major influence factors such as soil and relief properties of the catchments are seldom discussed. Paired watershed experiments, however, were limited to a size of 1–2,500 ha.

Modeling

In larger catchments it becomes increasingly costly and difficult to control the experimental boundary conditions and to measure precipitation and stream flow accurately. Thus in recent years the application of simulation models to quantify the effect of land use change on the hydrologic cycle has increased. The first water balance models were produced back in the late 1940s. In a more sophisticated manner, the development of hydrological models started in 1960s with the Stanford watershed model [41]. Until today the number of models and model systems as well as the number of different model concepts grew considerably as indicated in the overview given by Singh [42]. They have evolved in a number of different directions depending on the many purposes for which they are required [43, 44]. Generally speaking, nowadays there are three different approaches to modeling the landscape water balance:

1. *Physical-deterministic models*, which are based on the fundamental laws of physics (chiefly hydrodynamics and thermodynamics), chemistry, biology, etc.
2. *Conceptional models*, which take these laws into account in a simplified manner and also use empirical approaches
3. *Empirical-statistical models*, which are solely based on the empirically measured cause–effect relations of system inputs and outputs without trying to fathom the laws on which they are based

The transitions between the three approaches are in a state of flux. Moreover, hydrological processes always include both deterministic and stochastic characteristics owing to the unavoidable simplifications of

complex reality and the error occurring when capturing input data [45].

Depending on the model type and its purpose, different scales of temporal and spatial resolution are used. Compromises usually have to be made between the accuracy desired and the availability of data. If nonlinear processes are being studied (e.g., precipitation and runoff), hourly or daily steps have to be used, whereas for seasonal or annual properties monthly or even yearly steps suffice. The possible degree of spatial resolution ranges from highly aggregating approaches in which the study area is divided into a few subunits with similar geophysical properties ("lumped models") to models that as far as possible take into account the variability of spatial structures ("distributed models"). The scope for using a higher spatial resolution has improved with the advent of faster, more powerful computers, the development of geographic information systems, and – especially recently – the growing availability of data stored in a Geographical Information System (GIS).

Water balance models are used to depict the impact of land use changes on potential natural groundwater recharge (e.g., [46, 47]). Usually variants or scenarios are investigated, which are for instance based on assumptions concerning climatic change or the impact of political decisions (Table 3). If balancing is performed over the entire study area, only very pronounced land use changes will result in any considerable shifts in the simulated total runoff. What the list in Table 3 fails to show are any local changes, which in certain areas may well considerably exceed the means calculated. The algorithm used to introduce the land use changes forecast into the area also needs to be considered. Depending on local characteristics, the effect on further modeling exerted by a change in land use varies greatly. Assumptions regarding the spatial distribution of land use changes can be made by using plausibility considerations. Alternatively, models can also be used [9].

Hydrologic models can be useful tools to evaluate the effect of landscape patterns or land use change resulting from policy decisions, economic incentives, or changes in the economic framework [9, 50, 51]. One of the earliest works was from Onstad and Jamieson [52], who investigated the effect of land use modifications on runoff. A two-dimensional groundwater model has been applied in several Australian experimental catchments to quantify the response of the underlying aquifer to the removal of deep-rooted native vegetation [53]. The catchment response to clearing was assumed to be a function of the temporal pattern of the clearing, the proportion of the catchment cleared, the location of the clearing within the catchment, and the rainfall amount. Calder et al. [54] carried out a modeling study to determine the effects of land use change from natural forest to agricultural land on a large-scale catchment (124,500 km) in Africa.

Landscape Planning for Sustainable Water Usage. Table 3 Case studies on land use change and water yield [48]

Region	Scenarios in the case studies	Land use change	Simulated change in total water yield (%)	Reference
NE-Germany	EU agricultural reform	Change of 4% AL into forest, change of 32% AL into forest	−1, −10	[49]

		AL: 44 → 73%		
Hesse (Germany)	Agricultural policy: cessation of animal husbandry	Forest: 42 → 49%,	+2	[9]
		AL: 44 → 37%		
Saxony-Anhalt (Germany)	Analysis of land use conflicts in priority areas (agriculture vs. groundwater protection)	Change of 10% AL into forest, *Koethener Ackerland, Noerdlicher Mittelflaeming*	−9, −2	[47]

AL arable land

Lørup et al. [55] applied the lumped conceptual hydrologic model NAM in six medium-sized catchments (200–1,000 km) to assess the long-term effect of land use change in Zimbabwe. They stated that despite a significant increase in population density, there have been no major changes in the percentage of each land use type and thus there was no indication of increased surface runoff in the six catchments. The physically based model SHETRAN [56] was applied to characterize the influence of land use on catchment hydrology [57]. Results from those simulations show that the same land use change may have a significant effect on the hydrology of a lowland subcatchment, but an insignificant effect on the hydrology of the upland subcatchment. This underlines the necessity of spatially distributed modeling approaches for land use change studies.

Dunn and Mackay [57] discuss in detail the influence of vegetation type on evapotranspiration and its components' interception and transpiration for the Tyne Basin (>2,000 km) in northeast England. They outline the importance of physical soil properties for the nature of the hydrological response to variations in vegetation cover. Lahmer et al. [58] and Eckhardt et al. [59] addressed the problem of input data uncertainty for land use change studies in large catchments.

Another crucial point is the thorough validation of catchment models for predicting land use change. In large basins there are usually no experimental data for real land use change available. Thus the model calibration and validation is mostly restricted to measured stream flow data. Different validation techniques are discussed critically by Klemes [60] and Ewen and Parkin [61]. Additional information for model testing can be obtained by the application of base-flow separation algorithms, as for example, as proposed by Lyne and Hollick [62] or Arnold et al. [63]. Though one has to be aware that this method is empirically based and thus the applicability to catchments other than those of the original data set is limited, and the results should be interpreted with care.

Land Use as Controlling Factor for Water and Nutrient Dynamics

The investigation of the effect of land use change and land use patterns on hydrologic processes such as groundwater recharge or surface runoff provides information for the development of sustainable land use concepts and integrated environmental and river basin management as demanded by the landscape programs or the European Water Framework Directive (WFD [5]). There are numerous examples for studies described in literature where hydrological models are applied successfully for the simulation of the influence of land use changes on potential groundwater recharge or streamflow. Mostly variants or scenarios are investigated that are based on assumptions of climatic change or of the influence of political decisions. When simulating water balances for large areas, only considerable land use changes result in noteworthy shifts of the simulated total runoff. Depending on the selected model type, database, and regional site conditions of the study site, land use changes can affect the results (and also the further modeling) to varying degrees. The assumptions of land use changes can be made on the basis of plausibility considerations, or models can be applied [9]. Fohrer et al. [10] and Hörmann et al. [11] give an overview of the prospects and limitations of eco-hydrological models for evaluation of land use options in mesoscale catchments. The papers that they analyzed are classified into three categories: analysis of consequences of observed (or historical) land use changes on the water cycle, simulation of hydrologic consequences of land use change based on ecological and mainly economic scenarios, and finally optimization of land use according to economic or ecological criteria, where both components, hydrology and land use change, are simulated.

Lorz et al. [48] emphasize the need of an improved consideration of the spatial distribution and functionality of forests in river basin management. Their review of relevant papers has shown that forests, despite their frequent occurrence in temperate zones, play presently only a minor role in river basin management. In general, most of the studies highlight the positive effect of forests on water and nutrient fluxes in river basins. But hydrologists have also reported consistently flood events in or originating from forested areas. In context of the discussion on forest ecology and water quality it became obvious that forest ecosystems can be sources depending on system properties, time, and atmogenic pollution. The simulation of land use changes on water yield in forested river basins has been carried out in

a great number of research projects, but mostly without considering the spatial distributed function of forests. The objective of Lorz et al. [48] was thus to improve the consideration of spatial distribution of forests in river basins and its effect on water yield and water quality. The most promising approaches in the future are either spatial explicit models or integrated models with both improved forest modules and landscape positioning. The efficiency of these models could be proved by using virtual catchments. As a first conceptual approach towards the base concept of a virtual catchment, they propose a five-unit model (FUM), representing cross-sections with typical land use sequences. The basic idea of their model is to identify major process units and to implement them in the river basin modeling and management.

In much of Europe, the USA, and parts of Australia, increased inputs of especially nitrogen and phosphorus to land in the form of fertilizers, manures, and biosolids means that agricultural runoff now comprises a greater share of these nutrients in groundwater, rivers and lakes, and associated water quality problems [64, 65]. Numerous site-specific field studies have quantified the potential export of nutrients in agricultural runoff. But it is clear that to meet the requirements of end users, the research effort needs to shift towards developing suitable models that are based on expert knowledge to simulate the impact of land use and land management practices on diffuse source pollutant transport. Franko et al. [66] and Neubert et al. [67] give examples for the application of two different model systems: the process-based carbon-and-nitrogen-dynamics models, CANDY, and the (balance-oriented) whole-farm simulation model, REPRO, to determine land usage variants, which, employing the regional regulation potential, lead to a reduction of nutrient outputs into neighboring ecosystems. The hydrological effects were simulated with ABIMO (which is a runoff generation model) that was used to model data for groundwater recharge. This was then taken as a basis in conjunction with area-related nutrient balances to estimate nitrogen discharge by using the model CANDY (***Ca**rbon-and-**N**itrogen-**Dy**namics*; [66, 68]). With regard to the modeling and estimation of the scenario effects, extensive sensitivity analyses were carried out. As a result not only point estimates for the criteria values were generated but also probability distributions reflecting various kinds of data and model uncertainties [69]. The results of the studies presented by Volk et al. [70] and Franko et al. [66] were used as a basis for multi-criteria ecological-socioeconomic assessments described in Horsch et al. [71] and Klauer et al. [69]. The application of an alternative model combination of ABIMO and the model REPRO (Reproduction of Soil Fertility; Hülsbergen [72]) in this study area is presented in Neubert et al. [67]. Models such as REPRO provide efficient tools for evaluating both environmental and economic performance of farming systems. The results indicate an explicit dependency of the nitrate leaching on groundwater discharge and nitrate balance in relation to the variants of cultivation practice like organic, integrated, and conventional farming. The work shows clearly the influence of the quality and availability of data on the simulation results, whereas the model structure seemed to have less influence in this case study.

The experiences of different European and national projects dealing with the model-supported implementation of the WFD revealed that the available *integrated* model systems are still far from being suitable for operational applications with regard to water quality simulations [73–75].

However, complex transdisciplinary problems have to be tackled through implementation of WFD or other environmental directives. Hence, in order to achieve optimal working efficiency of the models in the management processes, it is required that they contribute information over a wide range of abiotic and biotic aspects of hydrology and water quality demanded by the decision makers, which cannot be achieved by individual groundwater, water quality, or erosion models. Consequently, the suitability of the publicly available river basin model Soil and Water Assessment Tool (SWAT) [76], the available database and the existing water quality monitoring network to adequately represent general trends in water quality changes resulting from various measures based on land use and management change in the intensively used Upper Ems Basin was checked by Volk et al. [18, 77, 78] and Ullrich et al. [78].

During the last years, increased cultivation of energy crops influences the landscape water and nutrient balance. Schilling et al. [79] showed that over the

last century, land use and land cover (LULC) in the US Corn Belt region shifted from mixed perennial and annual cropping systems to primarily annual crops. Historical LULC change impacted the annual water balance in many Midwestern basins by decreasing annual evapotranspiration (ET) and increasing streamflow and base flow. Recent expansion of the biofuel industry may lead to future LULC changes from increasing corn acreage and potential conversion of the industry to cellulosic bioenergy crops of warm or cool season grasses. Schilling et al. [79] used SWAT to evaluate potential impacts from future LULC change on the annual and seasonal water balance of the Raccoon River watershed in west-central Iowa. Three primary scenarios for LULC change and three scenario variants were evaluated, including an expansion of corn acreage in the watershed and two scenarios involving expansion of land using warm season and cool season grasses for ethanol biofuel. Modeling results were consistent with historical observations. Increased corn production will decrease annual ET and increase water yield and losses of nitrate, phosphorus, and sediment; whereas increasing perennialization will increase ET and decrease water yield and loss of non-point source pollutants. However, widespread tile drainage that exists today may limit the extent to which a mixed perennial-annual land cover would ever resemble pre-1940s hydrologic conditions. Study results indicate that future LULC change will affect the water balance of the watershed, with consequences largely dependent on the future LULC trajectory.

Scale Appropriate Application of Models for Integrated Ecological-Economic Assessments and Decision-Support

Integrated river basin and environmental management involve all management objectives related to the use, pollution mitigation, pollution rehabilitation, protection and rehabilitation of water bodies, as well as many other impacts on biodiversity, soil protection, water quantity, and quality in river basins or administrative units [80]. An integrated approach implies that relations between the abiotic and the biotic part of the various water systems, between ecological and economic factors, and between various stakeholder interests are considered in decision-making processes. It takes into account three often conflicting main dimensions: ecology, economy, and equity [81]. Directives such as the WFD, the NATURA2000 in Europe, or Clean Water Act (CWA) in the USA call for multidisciplinary approaches of river basin and environmental management. Hence, during recent decades a number of research projects have developed (spatial) decision-making support systems (DSS) for integrated water resources and environmental management (including socioeconomic analyses) with respect to groundwater management and flood prevention problems [80–87]. Most of them offer the possibility of drawing information from geographical information systems and/or supplying interdisciplinary multi-criteria analyses of the hydrological, ecological, and economic consequences of different management strategies, based on either pre-calculated scenarios or model coupling [88]. References [81] and [86–89] give examples and overviews of the development, application, and potential of different types of DSS. Giupponi [86] states that despite the many DSSs developed in the field of environmental management, the risk of Decision Support Systems failing to meet the challenge of real-world problems is reported to be high, and even the criteria for judging whether a DSS has been successful or not are often a matter of discussion (e.g., [90–92]). He emphasizes that there is a widely recognized need to develop new decision-support tools in this field, with greater attention to the needs of potential users and to identification of the application context.

An integrated approach to catchments, that is, administrative units, is essential that would include a necessary basis for balancing and reconciling conflicting interests. Therefore further development of integrated natural resource management is needed to incorporate land use, pollution leads, and vital ecological goods and services [1]. Planners and policy makers have the difficult task to intervene in complex human–natural systems. They cannot focus only on individual processes; rather it is necessary to address the system as a complex integral whole and think about economic values. To fulfill these requirements, tools such as DSS that integrate environmental, social, and economic concerns and that facilitate the involvement of interested parties in the formulation of strategies may be useful. Especially water is considered more and more as an economic good due to competing water use resulting in resource scarcity (e.g., [93–95]). Decision makers

need information about the economic value of water and the economic consequences of water management. The complexity of interactions between water, ecology, and the economy can be captured through formal, mathematical models. These models link relevant hydrological and biogeochemical processes to economic "laws" of supply and demand underlying the provision of scarce water services. Brouwer and Hofkes [95] edited a special issue on "Integrated hydro-economic modeling: Approaches, key issues and future research directions" in the journal of "Ecological Economics." They distinguish between main approaches: modular, holistic, and computable general equilibrium models. The latter top-down models counterbalance the traditional emphasis on bottom-up water engineering approaches. Key issues and future research directions in integrated hydro-economic modeling are discussed and illustrated through a variety of case study applications worldwide. Although the interaction works both ways, feedback effects of water changes on the economy and changes in the economy on the water system are often missing in practice.

The study presented by Rode et al. [96] includes the work on integrated nutrient transport modeling with respect to the implementation of the WFD that was done in the Weisse Elster Case Study, Germany. The implementation of the WFD can only be tackled by comprehensive environmental and economic assessments based on an integrated methodology and decision-support system. The methodology was developed within an interdisciplinary research project on the highly polluted Weisse Elster River basin, a large subcatchment of the Saale basin that is part of the UNESCO-IHP HELP program. The project focuses on nutrient management, river basin management, and decision making to achieve good ecological status of surface waters. From the modeling study using SWAT it can be concluded that the investigated organic farming scenarios do not ensure a considerable reduction in high nitrogen loads from the agricultural land of the studied catchment. Only the scenario on liberalization of the agricultural market leads to a considerable reduction in nitrogen loads due to large reduction of agricultural land use of 42.6%. The scenario analysis shows that sufficient reductions in nitrogen loads with respect to the ambitious goals of the WFD can only be achieved with a considerable change in agricultural land use. With regard to the river water quality modeling study it can be concluded that the impact of the most feasible measures on the concentration of inorganic nitrogen is quite low. Little effect on the yearly mean of inorganic phosphorus is also expected. The reason for this is that the autotrophic assimilation is low and the substance regimes between sediments and the water column are on average balanced, since the seasonal dependence of fixation through sorption or mobilization by desorption or erosion is preponderant. The parameter uncertainties are high and sometimes larger than the effect of the investigated river restoration management scenarios. The case study shows that easily applicable measures for the reduction in diffuse nutrient (especially nitrogen) loads may not be sufficient to reach the goal of good water quality status requested by the WFD.

Volk et al. [18] present the results of the FLUMAGIS project, in which they developed a spatial decision-support system (SDSS) to support the implementation of the WFD. The main objective of the WFD is the achievement of a good ecological and chemical status of the water environment (water bodies). This status corresponds to the limit value of Germany's Working Group of the Federal States on Water Problems Issues (LAWA) for water quality class II (3 mg/l total nitrogen). The rivers in the intensively cropped Upper Ems River basin (Northwestern Germany) show total nitrogen concentrations in excess of 5–10 mg/l. One objective of the project was to find a land use and land management scenario that would reduce the total nitrogen concentration to meet the WFD requirements for good ecological and chemical status [77].

Within the FLUMAGIS project, Volk et al. [77] developed consecutive land use and management scenarios on the basis of policy instruments such as the support of agro-environmental measures by Common Agricultural Policy and regional landscape development programs. The model simulations were done by using SWAT. Table 4 summarizes the agro-environmental measures that they considered in the model. They were developed successively in direction of a target scenario that finally would come close to the water quality objective of the WFD. The areas for the necessary land use changes were mainly chosen by catchment characteristics (permeability of the soils, groundwater table) and the degree of human impairment (river channel regulation, nutrient leaching).

Landscape Planning for Sustainable Water Usage. Table 4 Implementation of agro-environmental measures in the model

Scenario	Measure	Implementation in the model
1	Increase of pasture/decrease of arable land	Modification of the land use file (shape-files). Allocation of the land use type pasture on former arable land.
2	Extensification of pasture	Reduction of livestock density to 1.4 livestock units per hectare by modification of the management scenarios. Reduction of the amount of fertilizers.
3	Afforestation of arable land	Modification of the land use file (shape-files). Allocation of the land use type forest on former arable land.
4/5	Implementation of conservation tillage practices Extensification of arable land Modification of crop rotation schemes	No plowing, only cultivator and harrow (reduction of tillage depth), reduction of mixing efficiency. Reduction of the amount of applied mineral fertilizers accordant to 0.7 livestock units. Implementation of complex management scenarios over several years with short fallow periods.
6	Oxbow reconnection (improvement of river morphology) Riparian buffer strips	Increase of the river length on the HRU level. Modification of Manning's roughness coefficient "n" (CN_N(2)) for main channel flow. Modification of the parameter FILTERW
7	Abandonment of the floodplain use	Conversion of arable land and pasture in riparian zones to areas without management. Change of floodplain pasture into wetland (according soil and groundwater conditions).
8	Additional increase of pasture/decrease of arable land	Conversion of arable land to pasture (randomly chosen).

In order to achieve the good ecological status for nitrogen at the Upper Ems River, the nitrogen concentration has to be reduced by 50% of the mean annual average. This would require substantial, expensive changes of land use and land management intensity as well as of the river morphology. Figure 4a, b shows the current conditions and the target scenario (scenario 8) that comes closest to the requirements of the water quality class II for nitrogen.

In addition to river channel changes, this scenario includes reduction of arable land from 77.2% to 46% (13% organic farming), increase of pasture from 4% to 15%, afforestation from 10% to 21%, increase of protected wetlands from 0% to 9%, etc. However, this is not realistic from an economic point of view, since the drastic cuts for the farmers would be so strong that most of them would have to give up their farms. Agro-economic calculations have shown, for instance, that the mentioned changes in the floodplains alone would cost between 500 and 800 euro per hectare per year (31.6 million euro per year) [18] depending on regional soil qualities and management intensities. This measure is expected to result in intense conflicts with affected farmers [18].

Results of SWAT scenario calculations showed that drastic measures, which are unrealistic from a socioeconomic point of view, would be needed to achieve the water quality target in the basin. The example shows additionally that the achievement of the WFD targets is only possible with a consideration of regional landscape and land use distinctions. A related problem yet to be addressed is the general lack of measured water quality data with which to calibrate and validate water quality models such as SWAT. This adds considerable uncertainty to already complicated and uncertain situations. Thus, improved strategies for water quality monitoring, and data accessibility must be established.

Landscape Planning for Sustainable Water Usage. Figure 4
Current land use distribution and nitrogen concentrations (**a**) and scenario 8 (**b**) with the land use distribution and simulated nitrogen concentrations to achieve the good ecological status for the Upper Ems River. Note values include 0.26 mg organic nitrogen for (**a**) and 0.2 mg/l organic nitrogen for (**b**)

Future Directions

Landscape planning and sustainable water use can only be successful within integrated approaches. In this regard, integrated landscape and river basin management takes into account the three often conflicting dimensions of ecology, economy, and equity [81]. Finding a proper balance between the interests of different stakeholders requires understanding the effects of combined measures on multiple river functions [97]. Uncertain future conditions related to changing political priorities, economic development, and climate change influence the outcome of proposed alternatives. The decisions are inherently a political (and economic) matter, but resulting management plans need scientific underpinning and the support of local stakeholders prior to implementation. There is a need to (a) bridge the gap between the scientific knowledge and demand for information (that requires a combination of a wide range of expertise and data) and (b) make the information available for the analysis and presentation of promising strategies for integrated landscape and river basin management. The benefit of using DSSs in the complex field of integrated landscape and river basin management is that these systems enable comparisons of different land and water management strategies based on the effects on multiple objectives.

With regard to DSS, Volk et al. [98] analyzed benefits and shortcomings of four recently developed decision-support systems. The analysis elaborated on the following aspects: (1) application area/decision problem, (2) stakeholder interaction/users involved,

(3) structure of DSS/model structure, (4) usage of the DSS, and finally (5) most important shortcomings. On the basis of this analysis, they formulated four criteria that are considered essential for the successful use of DSS in landscape and river basin management. The criteria relate to (1) system quality, (2) user support and user training, (3) perceived usefulness, and (4) user satisfaction. Volk et al. [98] could show that the availability of tools and technologies for DSS in landscape and river basin management is good to excellent. However, their investigations indicated that several problems have to be tackled. First of all, data availability and homogenization, uncertainty analysis and uncertainty propagation, and problems with model integration require further attention. Furthermore, the appropriate and methodological stakeholder interaction and the definition of "what end users really need and want" have been documented as general shortcomings of all four examples of DSS. They propose an iterative development process that enables social learning of the different groups involved in the development process, because it is easier to design a DSS for a group of stakeholders who actively participate in an iterative process. Volk et al. [98] also identified two important lines of further development in DSS: the use of interactive visualization tools and the methodology of optimization to inform scenario elaboration and evaluate trade-offs among environmental measures and management alternatives.

In general, new approaches to long-term water planning and management that incorporate principles of sustainability and equity are required and are now being explored by national and international water experts and organizations. Hence, Gleick [99] offered seven sustainability criteria for water planning (Table 5).

These sustainability criteria provide a framework for prioritizing competing interests and for making decisions about future water use and management. The first two criteria require that basic allocations for humans and ecosystems are identified and met, which are to be satisfied before other demands. Thus, the approach suggested by Gleick [99] defines criteria for basic needs as recommended by Agenda 21 of the United Nations. Besides setting out quantity and quality requirements, they also set an upper limit to water use and provided some institutional guidance.

Landscape Planning for Sustainable Water Usage.

Table 5 Sustainability criteria for water planning [99]

A basic water requirement will be guaranteed to all humans to maintain human health.
A basic water requirement will be guaranteed to restore and maintain the health of ecosystems.
Water quality will be maintained to meet certain minimum standards. These standards will vary depending on location and how the water is to be used.
Human actions will not impair the long-term renewability of freshwater stocks and flows.
Data on water resources availability, use, and quality will be collected and made accessible to all parties.
Institutional mechanisms will be set up to prevent and resolve conflicts over water.
Water planning and decision making will be democratic, ensuring representation of all affected parties and fostering direct participation of affected interests.

Demographic change Refers to new demographic developments that bring sustained sub-replacement fertility, a multitude of living arrangements other than marriage, the disconnection between marriage and procreation, and no stationary population. Instead, populations would face decline if not complemented by new migrants, and they will also be much older as a result of lower fertility and additional gains in longevity. Migration streams will not be able to neutralize aging, but stabilize population sizes. Demographic change brings new social challenges such as aging, integration of immigrants and other cultures, less stability of households, and high levels of poverty or exclusion among household types like single persons of all ages or single parents. It brings alterations in per capita housing and transport demand.

Ecosystem services Society benefits from a multitude of resources and processes that are supplied by natural ecosystems and landscapes. Collectively, these benefits are known as ecosystem services and include products like clean drinking water or recreation area and processes such as the decomposition of wastes. In 2004, the United Nations 2004 Millennium Ecosystem Assessment (MA) formalized ecosystem services and grouped them into four broad categories: provisioning, such as the production of food and water; regulating, such as the control of climate and disease; supporting, such as nutrient cycles and crop pollination; and cultural, such as spiritual and recreational benefits.

Governance Governance is the activity of governing. It relates to multi-actor and multilevel decision-making that define expectations, grant power, or verify performance. It consists either of a separate process or of a specific part of management or leadership processes. In the case of a nonprofit organization, governance relates to consistent

management, cohesive policies, processes, and decision rights for a given area of responsibility. In case governance refers to land use, it deals with land management.

Landscape planning Landscape planning puts landscape ecology into a spatial planning context. It focuses on landscape function and ecosystem service assessment on different spatial scales. Landscape planning develops strategies for sustainable land use systems including the whole range from natural, cultural landscapes to impacted or devastated areas.

Land use Land use is the human modification of the natural environment, surface, or wilderness into built environment such as fields, pastures, and settlements. Urban land use is characterized by a particular high degree of imperviousness.

Perforation Development of patchwork settlement structures without a compact core and related creation of low-density counter settlements with implications for lower sealing rates, building and population densities. The spatial cohesion of perforated areas is low.

Shrinkage Shrinkage is understood primarily as the quantitative process of population decline in an area which might be the result of very different processes such as deindustrialization, demographic change, or even natural hazards.

Sprawl Urban sprawl is a multifaceted concept, which includes the spreading of impervious surface and built-up area outward of a city and its suburbs to its outskirts to low-density, car-dependent development on rural or virgin land, with associated design features that encourage car dependency.

Sustainability Sustainability is the capacity to endure. In ecology, it describes how biological systems remain diverse and productive over time. For humans, it is the potential for long-term maintenance of well-being, which in turn depends on the well-being of the natural world and the responsible use of natural resources. It includes the maintenance of landscape functions, ecosystem goods and services.

Definition of the Subject

When thinking about sustainability, it is mainly about how to keep intact nature and environmental resources for either future generations and/or, more in terms of environmental justice, for other parts of the world. Land use and spatial planning focus on how to minimize negative effects of urban and industrial growth. Set against this context, urban shrinkage represents a new challenge. This is true due to the fact that one has to deal with the opposite phenomenon of growth – population decline and accompanying processes of de-densification – which, unemotionally, also asks the same questions as even mentioned for growth: How could land use development be steered in order to ensure quality of life of the population under conditions of decline? How high-quality and sustainable urban livelihoods can be developed? Are there visions for sustainable shrinkage?

Resource consumption is a problem particularly in cities due to the concentration of population – that is consumers of environmental goods and ecosystem services. Since some years, more than half of the world population lives in cities. And, what is more, >200 cities worldwide, mostly in Europe, Russia, Japan and the US, are shrinking: they are losing population. Shrinkage and declining population numbers do not mean an automatic decrease of natural resources consumption such as land, energy, or water because the per capita requirements on environmental resources, ecosystem services, and housing space are increasing. Also, in shrinking cities, household numbers increase. In consequence, population losses along with rising per capita housing space lead to further land consumption and enlargement of, for example, transport and infrastructure. Also, in shrinking cities, sprawling settlement development continues because of specific housing preferences such as single family houses and spacious housing with backdoor garden.

Since shrinkage does not follow the logics of growth, there are no receipts for how to sustainably develop or plan a shrinking city. This entry will show that shrinkage appears in many different shapes and argues that there will not be a "one-size-fits-all" or textbook answer to this question. So doing, the entry addresses the relationship between urban decline, socio-demography, infrastructure, land use, and ecosystems, and discusses causes and consequences of shrinkage in the light of sustainability. It ends up with showing how actors in cities react to shrinkage in terms of rethinking their visions, instrumental settings, and strategic planning.

Introduction: Shrinkage and Sustainability – Setting the Scene

Urban Shrinkage

Shrinkage affects many cities across the world, especially old industrial areas (America's Rust Belt, British Midlands, Germany's Ruhr Valley, eastern part of Germany; [1, 2]). The phenomena of urban shrinkage and its concomitant industrial blight, low investment rates, depopulation, and low housing demand can be vividly exemplified in the landscape: dilapidated residential buildings and estates, extensive brownfield and derelict commercial sites, streets with vacant storefronts, underutilized social and technical infrastructure, and neglected parks and squares [3]. Shrinking cities often hold large brownfield sites, particularly in their old built-up inner parts [4].

Urban shrinkage appears in many forms and dynamics. Since their very early history, cities across the world have already seen phases of decline [5]. The same is true if one narrows the focus to look at the recent decades of urban development. Already throughout the entire twentieth century up to the present day, urban shrinkage has become reality for many cities in Europe, Russia, Japan, and the eastern US ([6]; cf. Fig. 1).

Recent studies provided evidence for the fact that about 40% of all European cities >200,000 inhabitants have lost population in a short-, medium- or long-term period for different reasons (for a quantitative analysis, see studies by [6] or [7]). Therefore, urban shrinkage has become the focus of international research and debate, not least because of cross-national projects (e.g., Shrinking Cities, 2002–2008; ShrinkSmart, 2009–2011) or the establishment of scholarly networks (e.g., the Berkeley Cities International Research Network SCIRN; [8]). One of the exceptional cases of urban shrinkage is eastern Germany, which lost between 10 and 20% of its residents in a period of 10 years (mean value for big cities from 1990 to 1999 is about 16%). Thus, in the following, eastern Germany will serve as an example case when analyzing processes and patterns of shrinkage.

How does urban shrinkage relate to sustainability and resource consumption in urban regions? A recent analysis of the relation of population and household development of 195 European cities from 1990 to 2000

Landscape Planning/Design of Shrinking Landscapes. Figure 1
World map of shrinking cities with more than 100,000 inhabitants (adopted from the "Atlas of shrinking cities" by Office Oswalt, [1])

Landscape Planning/Design of Shrinking Landscapes. Figure 2

Left: Annual growth rate of total population (P), number of households (HH), per capita housing space (HSp), and urban land area of shrinking cities across Europe 1990–2000. *Right*: Projection of total population, number of households, and urban land area of shrinking cities in Europe from 2001 to 2020. The annual growth rates were computed for each variable x as Δx from t_0=1990 to t_1=2000, for instance, for the number of households HH: $\Delta HH = HH(t_0) - HH(t_1)$. Assuming that the average aggregate population, the average household size, the average rates of urban and commercial land take in European cities in 2020 remain at the level of 2000 (t_1), the aggregate population at t_2 was estimated as $Pop_{t_2} = Pop_{t_1} + GR_{a_{1990-2000}}$ where $R_{a_{1990-2000}}$ is the average annual growth rate 1990–2000 [9]

to the growth of urban land consumption and housing space [9] found a significant share of cities facing declining population and decreasing household numbers. Nonetheless, the urban (= impervious) areas within the boundaries of these declining cities have continued to spread. No reduction of natural resource consumption in terms of returning sealed surfaces back to their natural states was observed (Fig. 2).

In addition to that, [9] identified an increase in per capita housing space, which also counteracts a reduction of land consumption. A linear projection of population, household numbers, and urban land up to 2020 shows that, exemplified at European cities, urban – that is mostly impervious surface – areas will face further land consumption, regardless of whether population and household numbers increase or decrease. Therefore, the global problem of unsustainable resource consumption seems not to be "simply" solved by population shrinkage.

Urban Sustainability

The concept of "sustainable development" evolved in response to the socio-environmental impacts of economic activities. Already in 1987, the Brundtland report framed it as "meeting the needs of the present without compromising the ability of future generations to meet their own needs" (World Commission on Environment and Development). The application of this concept to urban regions and urban land use development raises many questions. This is, firstly, due to the diverse concept of sustainable development, which combines economic, social, and environmental goals, both locally and globally, and in both the short and longer term [10]. And secondly, because the nature of the urban areas is generally a complex mix of drivers, pressures, and processes in many different sectors, at different spatial scales [11]. In particular, the peri-urban role is as a hinterland and support system for urban core activities [12]: food is produced there, recreational facilities are given, energy is provided, and drinking water delivered [13, 14].

There is also a global dimension to the urban sustainability agenda, which is still dominated by growth: In the next 40 years, current projections show a rapid growth in the urban areas of developing countries of up to 3 billion people [15]. Current trends show that

a majority of urban residents will live in slums or chaotic settlements lacking basic infrastructure [16]. Much of this "urban" development is likely to be in peri-urban areas, or rapidly metropolitanized peri-rural areas [17]. However, next to this spreading growth, demographic aging and low-rate fertility will establish a new urban trajectory also in the developing world. This trend currently has been already reached cities in India or China [18, 19].

When thinking about sustainability, keeping intact nature and environmental resources for either future generations and/or, more in terms of environmental justice, for other parts of the world are talked about. Landscape and regional landscape planning focuses on how to minimize negative effects of urban and industrial growth [12, 20]. In terms of sustainability, urban shrinkage represents a new challenge because one has to deal with the opposite phenomenon of growth – decline and accompanying processes of de-densification and land use perforation – and focus on the following questions: How could land use development be steered in order to ensure quality of life of the population under conditions of shrinkage? Is it possible to direct land preparation toward the inner parts of shrinking cities? Are there visions for sustainable shrinkage?

Premises of Shrinkage

Urban shrinkage has been approached using different ways (see review by [8]): Some scholars interpret shrinkage as a decreasing population development in the urban core (city) as part of wider shifts in the spatial organization of larger urban regions (for example, between the urban core and the peri-urban hinterland) in the course of which existing built environments are devalorized, mainly in economic terms, and made obsolete [21–23].

Others discuss urban shrinkage as an inevitable result of uneven economic development, emerging as something rather natural that is deeply rooted in the nature of capitalist economies [24] and the underlying dynamics of the territorial division of labor [25, 26]. In fact, many shrinking cities exist because of the postindustrial shift from manufacturing (II. Sector) to service industries (III. Sector) and the IT branch (IV. Sector) followed by resulting unemployment and outmigration (such as Pittsburgh and St. Louis in the US, Manchester or Liverpool in UK). In eastern Europe and the former Soviet Union, the collapse of socialist systems led or at least importantly contributed to the decline of urban regions there [2]. Still another explanatory approach discusses urban shrinkage in the light of demographic change and relates it to low-fertility rates, changes in the household formation, and migration impact (see here [27, 28]).

In this entry, shrinkage is defined as the quantitative process of population decline. Population decline is represented by both natural decline (i.e., death surpluses) and losses by out-migration (due to suburbanization, intra-regional migration, emigration). It is frequently used as the main indicator in research on urban shrinkage, which makes the findings presented here in this respect easily comparable with other studies [1, 5, 6, 29]. Overall, shrinkage processes have drained essential resources from the urban regions (mostly the core cities), leaving the cities with a diminishing fiscal base [30].

Urban shrinkage affects the physical space, the society of a city, and the surrounding ecosystems (as well as landscapes) whose mutual fit is diminishing; this leads in turn to phenomena such as mismatches of supply and demand in various respects [31]. Since shrinkage is also a spatial phenomenon, it is important to differentiate between urban shrinkage as a process and its results that are seen as reconfigured or reshaped urban structure or patterns [32]. Urban shrinkage impacts on nearly every sphere of urban life: municipal budgets, land use and urban planning, natural resources, ecosystem services, infrastructure and amenities, housing market and housing mobility, labor market and employment, residential composition, and social inclusion and cohesion. This makes shrinkage a challenge for both landscape planning and sustainability research.

Consequences of Shrinkage on Sustainability

Shrinkage Patterns and Consequences for Urban Land Use

Population decline leads to a decrease in population density and to an oversupply/underuse of urban, residential, and commercial land, infrastructure, and services. Shrinking populations need fewer and modified services and amenities according to the need of the remaining, often aging, population [32]. This leads to

problems for both the public and private sector: Underuse of the building stock leads to housing and commercial vacancies and to a more rapid dilapidation of unused buildings [33]. Whilst in some places, buildings are demolished to "balance" the housing or real estate market, in other places they simply become unusable after a certain time of not being used. [34] introduced the term of "land use perforation " in order to describe the scattered land use development in the inner parts of shrinking cities: Fig. 3 displays a stylized example of land use perforation in comparison of dense (left) and compact (center) urban forms. The simulation results show that despite population decline and decreasing demand for housing space in the inner city, land consumption at the urban periphery continues.

Table 1 provides a detailed overview on the most important processes and impacts of urban shrinkage. It gives a short explanation of the underlying processes. Figure 4, developed based on the Table 1 findings, shows that most of the processes are interrelated and shape the specific appearance or trajectory of shrinkage in a particular city [35]. It shows the fortunes of urban neighborhoods as home or place to work which depend on their attractiveness under the condition of supply surplus, on ownership structures, housing policies, and the local economic situation of enterprises and retail.

Compared to the regular patterns of land use perforation produced by the stylized model given in Fig. 3, often, differences between neighborhoods in a shrinking city vary on a small scale within the urban area [36]. This makes it extremely difficult to identify an overall picture or specified model of urban shrinkage and its impact on the city as a whole or land use patterns in a larger scale as well as in the future [2, 37].

In consequence, the change of land use causes an increasing proportion of derelict land or brownfields within the inner parts of the city. This can foster out-migration decisions of those who do not want to live close to dilapidating building stock or areas of urban wilderness [4, 38]. This cycle will reinforce itself over time and lead to a steady decrease of population density either in specific parts of a city (Fig. 5 "perforated city"), in the central (Fig. 5 "disperse city") or peripheral parts (Fig. 5 "compact city"). In addition to such a patchy way of shrinkage, a widespread and overall decrease of population density across the entire urban area can be found [5].

The project "Leipzig 2030" [39] compared population densities of specific housing forms under conditions of high and low demand (Table 2). Low demand leads to vacancies in the buildings and to a shift of lower population densities in the city. So, for example, partial vacant, old built-up multistory estates almost "reach" population densities that are typical for terraced row houses. This is important for infrastructure development, as, normally, population density determines the network of social and technical infrastructure in cities.

Landscape Planning/Design of Shrinking Landscapes. Figure 3
Stylized representation of urban form: (*left*) a medium density built-up town, (*center*) a very compact city, and (*right*) urban land use perforation. Blue houses represent the built-up area, red patches newly prepared peri-urban land, green patches green area, and brown patches other types of land in the rural surroundings (NetLogo model and draft: D. Haase)

Landscape Planning/Design of Shrinking Landscapes. Table 1 Processes and impacts of urban shrinkage (adopted from [35])

Process/Impact	Explanation
Decrease in density	Population loss and out-migration lead to a decrease in the number of inhabitants of the affected areas and, subsequently, to a decrease in residential, commercial densities.
Increase in housing and commercial vacancies[a]	Decreasing demand leads to supply surplus and an underuse of housing stock, commercial stock, and, subsequently, to vacant stock.
	Vacancies in shrinking cities can affect also renovated or even new build stock due to a mismatch of supply (investment) and real demand (use).
Underuse of urban structures and infrastructures	Population losses and decrease in densities lead to an oversupply of urban structures (see above vacancies) and infrastructures such like schools, kindergartens, public transport, etc.
	Oversized infrastructures have to be either maintained without being used or closed or demolished.
Increase of unused (built) urban land	Due to decreasing densities and increasing underuse or nonuse, the share of unused built urban land increases.
	Demolition activities are necessary and being done.
	Unused built urban land can be vacant buildings, urban brownfields on former industrial, commercial, railways sites, etc.
	Unused built urban land develops to "new urban wildernesses" or even "forests".
Perforation of urban structures	Demolition, abandonment of places and uses within a city lead to the dissolution of the street or block grid of a city or urban area due to vacant lots and brown- resp. greenfields that separate or divide built lands (perforation).
	Perforated areas are characterized by a large percentage of vacant areas within an urban territory or city.
Changing sociodemographic structure of the residential population	Population losses and selective out-migration lead to aging, changing household structures, and a "blurred" age group distribution.
Increase in socio-spatial fragmentation and residential segregation	Selective out-migration and population losses might lead to a "blurred" socioeconomic structure of the remaining inhabitants.
	In shrinking cities, there are often relations between dilapidating areas with high housing vacancies and a concentration of disadvantaged population groups living there.
	Shrinking and resurging areas are situated closely to each other (= rising small-scale fragmentation).
Change in housing mobility within the city and its region	An oversupply of housing might lead to a higher housing mobility and a greater choice for a number of residential groups.
	The level of housing mobility increases due to the greater choice and the good opportunities to get a better flat at many places in the city.
	Vacant housing offers the opportunity for transitory housing, which might become more and more important for residential areas with housing oversupply.

Landscape Planning/Design of Shrinking Landscapes. Table 1 (Continued)

Process/Impact	Explanation
Decrease in municipal budget	Happens due to the decrease in tax revenues as a consequence of population losses. Results in many cases in an increasing dependency on public money.
Need of new planning schemes	Growth-oriented planning schemes have to be replaced by a strategy that aims at the coping with urban shrinkage, either in a long-term perspective or as a phase of urban development that has to be quickly overcome (depending on the causes of shrinkage and the chances of the particular city to reach regrowth).
Shrinkage of the local labor market	Decrease in employment and jobs leads to a decreasing demand on land used for industrial and commercial activities.

[a]Housing and commercial vacancies = housing and commercial stock that is inhabitable and useable but not inhabited or used; perforation = dissolution of the street or block grid of a city or urban area due to vacant lots and brown- resp. greenfields that separate or divide built lands

Landscape Planning/Design of Shrinking Landscapes. Figure 4
Compilation of social science indicators about shrinkage, its drivers, processes, and impacts (draft: D. Haase)

Effects on Socio-Demographic Sustainability

Can a city consistently lose population and yet maintain a high quality of life, human well-being, and social equity for all groups of residents? This paper argues it cannot in case planning does not counteract the following trends discussed in the literature or shown by statistical data: Urban shrinkage leads to shifts in the population structure since out-migration is almost always selective and often removes the younger and well-educated parts of the population leading to an

Landscape Planning/Design of Shrinking Landscapes. Figure 5
Stylized urban-to-rural gradient of growing (*black* line) and shrinking (*dotted* line) population development (*upper* diagrams) and respective impacts on urban fabric density (draft: D. Haase). Such fabric densities were already observed in several eastern German but also US cities [1]

Landscape Planning/Design of Shrinking Landscapes. Table 2 Population density of different housing form under conditions of high and low demand [39]

Housing form	Old built-up multistory high demand	Old built-up multistory low demand	Prefabricated multistory high demand	Prefabricated multistory low demand	Row houses	Single houses
Population density (inhabitants/km^2)	149	80	230	75	55	37

enforced aging of the remaining population (cf. again Table 1; Fig. 7b). The same happens when a city loses population due to death surpluses [40]. In shrinking cities, there is often a concentration of neglected population groups such as the unemployed, poor or low-income groups, and foreigners or ethnic minorities ([2]; Fig. 7c). Moreover, the overall household size is declining and accompanied by a temporary increase of the household number (cf. argumentation by [41] and [42]; Fig. 6).

This brings about challenges for social cohesion and may fix and strengthen patterns of socio-spatial and residential segregation and poverty concentration in the respective city [43]. Selective out-migration also has consequences for the labor market since skilled labor becomes scarce [8]. Here, the declining attractiveness of a city can even lead to an accelerated population loss and thus start a vicious circle [33]. In shrinking cities, high unemployment and decreasing investment are closely related to each other, which makes these cities less and less attractive for both in-migrants and developers and forces them, in many cases, into an especially developer-friendly, neoliberal policy to attract investment. This in turn demands low wages and high land consumption at the urban periphery [38, 44].

Figure 7 provides a mapped vision of socio-demographic and land use changes provoked by

Landscape Planning/Design of Shrinking Landscapes. Figure 6
Development of the total number of households in the shrinking eastern German urban region of Leipzig-Halle measured for 1990–2005 and simulated until 2025 (own analysis based on data by the German Federal Agency for Spatial Planning). The figure shows that particularly the number of large – that is 3 and more person households (3–5P) – will steadily decline whereas one (1P) and two person households (2P) still grow for a while. This is not an effect induced by shrinkage but by demographic transition processes. Both processes overlap in shrinking urban regions

shrinkage in Germany for 2020 [45] when it is defined as population decline: Fig. 7a shows the overall population decline in shrinking regions. Figure 7b then provides evidence that those regions faced with strong population decline – that is northeastern and central eastern Germany – age dramatically. Due to outflow of the young and well-educated people, the unemployment rate increases (Fig. 7c) – this process reinforces the aging. In consequence, settlement and transport development weakens (Figs. 7d and e), which is not by far a problem for the regional sustainability. Thus, reinforced processes of shrinking shape larger regions such as given in Fig. 7f.

Effects on Infrastructure

As far as urban space and its amenities and infrastructure are concerned, population losses bring about a decrease in density and an increasing underuse of infrastructure, urban land, and amenities [46]. Shrinking populations demand fewer services and amenities leading to problems for both the public and private sectors. Underuse of the building stock leads to housing and commercial vacancies and to a more rapid dilapidation of unused buildings [47].

So, for example, shops have to close when there is no longer enough purchasing power, and in most cases public infrastructure sees a thinning-out process – the frequency of services decreases and selected stops and trajectories are close down [48]. Local suppliers of water and electricity face a decreasing demand, which might lead to rising costs for those who still live in areas with a shrinking population, as they still have to cover the maintenance costs of the infrastructure system [49]. Whilst to some extent a decreasing building stock density leads to "relaxation" for a densely built city, at a later stage, it might lead to a fragmentation and even the aforementioned perforation of urban space in terms of dissolution of the street or block structure due to vacant lots [33].

The – at least temporary – result of shrinkage, as discussed in the previous section, is a pattern of (newly) built-up area in rather close vicinity to vacant housing. City intervention programs finally lead to

Landscape Planning/Design of Shrinking Landscapes. Figure 7
Changes of the spatial patterns of socio-demographic impacts of population decline exemplified for Germany for the time span of 2000–2020 (BBSR, 2005): Legends in (**a**), (**c**) and (**f**) range from red = very positive to blue = very negative; Legend (**b**) is red = very high to yellow = moderate; Legends of (**d**) and (**e**) is brown = significant to beige = nearly zero. In figure (**f**), the dotted areas mean an overdimensional aging

the partial demolition of the vacant housing stock and to land use perforation [33, 50]. This pattern of vacant, demolished, and new housing poses challenges for urban infrastructure provision. This is obvious for network-dependent infrastructure, like water, sewage, or electricity: Vacant houses no longer need supply of water or electricity or a transport for waste water, so that the pipes and cables leading to this house are no longer used. In an area with a larger proportion of vacant houses, underutilization can pose severe problems for maintenance of the service for the whole area [51, 52].

Social urban infrastructure like schools, kindergartens, as well as roads and public transport also are influenced by vacancy. All of these infrastructures are optimized for a certain demand structure in an area, usually determined by population density and commercial or industrial activity. At least, efficiency decreases in areas with higher rates of vacancy [2, 49]. At the worst, an area might enter a vicious cycle of declining population, underutilized and then dismantled infrastructure, so that the area gets less attractive. Thus, even more residents relocate to another part in the city [52]. Moreover, underutilization causes toxic effects and water resources pollution [46, 49]. In the years to come, housing service and maintenance costs are likely to rise in shrinking or perforating communities. In shrinking cities, lower residential densities may demand a smaller road network. Ironically, the demand for public transit could increase in shrinking cities as populations tend to be increasingly poor and increasingly without access to private transportation [2].

To avoid or at least limit higher ancillary costs and the consequent worsening of local conditions in the municipalities affected, low-cost urban renewal strategies of the spatial adaptation of the technical urban infrastructure need to be set on the agenda (examples are given in Table 3). The pure demographic aspect that a change of household structures and sizes arises, independent from growth or shrinkage, implies further changes in water and energy use [46].

Effects on Ecosystems

Turning to the positive side effects of shrinkage in inner city and peripheral areas – which arguably contribute to urban sustainability – demolition and resulting brownfields should be understood as a chance for ecological restoration and development of green networks in city regions [4]. [53] and [54] found a positive correlation between the amount of urban green and the habitat suitability of urban breeding birds (such as for the Green woodpecker *Picus viridis*). Generally, urban fallow lands (such as shown in Fig. 8) are seen as niches for rare specialist species [55]. The study by [54] reports particular high neighborhood densities of breeding birds in the old built-up housing areas of the inner parts of the city. Thus, demolished sites should be left partially open in order to develop long-term hotspots of urban biodiversity.

In order to measure biodiversity effects of shrinkage, a number of recently demolished sites allocated in a densely built-up and socialist prefabricated housing estates of the eastern German city of Leipzig had been

Landscape Planning/Design of Shrinking Landscapes. Table 3 Adaptation of infrastructure networks to shrinking or perforating contexts ([33]; adapted)

Form of adaptation	Land use and transportation impact
Increasing accessibility	Increase in traffic and road network demand
Reduction	Decrease in traffic and road network demand
Centralization	Decrease in traffic and road network demand
Decentralization (local networks)	Increase in traffic and road network demand
Temporal mobile structures	Optimization of spatial structures
New structures and substitution	No effects for spatial configuration but for total net consumption

Landscape Planning/Design of Shrinking Landscapes. Figure 8
Images of demolished sites within an old built-up residential area: a recently demolished site under spontaneous succession and two planted sites serving for transition and recreation purposes now

analyzed in terms of their spatial shape, configuration, and the resulting habitat quality for an open-land indicating bird species, Whitethroat (*Sylvia communis*). For the comparison of pre- and post-demolition status of about 50 sites, the following indicators have been used: Largest Patch Index (LPI) of open land uses, Edge Density (ED), Habitat Suitability Index (HSI), and Shannon Diversity Index (SHI). In doing so, LPI is defined as

$$LPI = \frac{\max\limits_{j=1}^{n}(a_{ij})}{A} * 100$$

where a is the area of single patches and A the total area. The edge density is

$$ED = \frac{\sum\limits_{k=1}^{m} e_{ik}}{A}(10,000)$$

where ED is edge density, A the total area, and e the edge vector. Finally, the Shannon diversity is formally according to [56]

$$SHDI = -\sum_{i=1}^{m} p_i \ln p_i$$

where p is the single patch. The HSI had been calculated using the approach of the ecological niche which is formalized the $\sum$ of cells with a certain probability of species presence [53, 57]. For calculation and mapping purpose, the *Biomapper* software tool was used [58].

The results of the study are shown in Fig. 9 [59]. Edge density and patch size are the variables that most benefit from selective, single house, or block demolition compared to only slight changes in Shannon diversity due to the uniform grasslands that emerged after demolition at many sites, particularly in the prefabricated peripheral districts. For species like the Whitethroat, demolition seems to offer an increase of its preferred open habitat structures (HSI values in Fig. 9).

However, general positive or negative effects of shrinkage for urban ecosystems and biodiversity are not verified yet through empirical studies. In particular residential vacancy, simple land abandonment (excluding a de-sealing) and perforation are not subsequently followed by positive effects for nature and ecosystems. On the contrary, inefficient solutions could lead to higher environmental impact and more land consumption in shrinking landscapes when, despite an existing urban brownfield, open land at the periphery becomes sealed [4]. Processes and forms of urban perforation are assumed to have the potential to considerably contribute to structural enrichment and an increase in edge densities [60]. They let one further think about a bringing back of nature to former densely populated and built urban centers. At least "wilderness ideas" [38, 61] in urban landscapes for recreational and educational purposes are in discussion among urban planners and landscape architects.

Shrinkage in terms of demolition and land use perforation has also effects for the water regulation flows in the city such as surface runoff and evapotranspiration since they create potentials for de-sealing [62]. [50] found for demolished and regreened sites in Leipzig

Landscape Planning/Design of Shrinking Landscapes. Figure 9
Largest Patch Index (LPI open) of open land uses such as park, allotment, courtyard, brownfield, wasteland, etc., Edge Density (ED), Shannon Diversity and Habitat Suitability Index (HSI) for a range of recently demolished sites in Leipzig – a comparison of the pre- (2005) and post-demolition (2009) status [59]

a decrease of the share of direct surface runoff and a higher water on-site percolation. The more the urban landscape gets perforated the higher the in situ water sink potential is.

Concerning carbon storage , shrinking cities are of particular interest: they have a high potential for urban reconstruction and new green space (also as brownfields) are abundant and development pressure is low [54]. Newly planted trees unquestionably sequester atmospheric CO_2 as they grow [63–65]. As promising results of a pilot case study by [54] impressively show, tree planting at demolition sites in shrinking cities can be viewed as one contribution to the many efforts that cities have to make in order to decrease their carbon emissions.

Landscape Planning/Design of Shrinking Landscapes. Table 4 Impact of planning policies on climate regulation indicators compared to values of 2000: affected areas [km^2] for the shrinking urban region of Leipzig [66]. Urban renewal policies in bold

Climate impact	Mining redevelopment	Urban renewal	Municipal development plans	Economic land take	Green corridors	Green ring around the city
f-evapotranspiration: no change; emissivity: higher	0.0	**0.0**	8.9	0.0	0.0	0.0
f-evapotranspiration: no change; emissivity: lower	0.0	**0.0**	14.7	1.1	177.0	110.3
f-evapotranspiration: higher; emissivity: no change	0.0	**0.0**	0.0	0.0	0.8	0.0
f-evapotranspiration: lower; emissivity: no change	0.0	**0.0**	0.1	0.0	0.0	0.0
f-evapotranspiration: higher; emissivity: lower	33.0	**6.5**	13.9	0.0	12.5	53.6
f-evapotranspiration: lower; emissivity: higher	0.0	**0.0**	48.5	17.0	15.9	0.9
f-evapotranspiration: higher; emissivity: higher	0.0	**0.0**	0.0	0.0	0.0	0.0

No change	999.7	**1026.2**	946.6	1014.6	826.3	868.0

In more general terms, next to the sequestration of CO_2 urban green can also put shade trees on vacant land [2] or cools the air by evapotranspiration fluxes [66]. To measure the climate regulation potential of urban renewal and development policies, an emissivity index value can be used for each land use in order to show differences in thermal emissions between land uses. The f-value is an approximation for the evapotranspiration potential of a land use class and therefore for emitting latent heat rather than sensible heat [66]. Table 4 shows the positive climate regulation contribution of urban renewal policies in consequence of shrinkage: They provide a higher vapor content in the air and release less heat emissions from the urban surface.

Response to Shrinkage

Modes of Collaboration and Governance

To what extent can existing planning tools used in growing communities be adapted to be used in a shrinking environment? And, secondly, how do planners, policy makers, citizens, businesses, and others operate within a shrinking city, how do they conceptualize population decline, how do they manage the physical changes that result from shrinkage, and what can they do to plan more effectively for shrinkage? Shrinking cities might offer a paradigm shift from growth-centered planning to a more careful and place-based approach toward more livable cities [2]. But, does shrinking cities planning mean making them greener, more compact, and thus sustainable?

In a shrinking city, spatial planning strategies to deal with the simultaneousness of urban restructuring and population shrinkage lay a focus on enhancing the quality of life in the city as a way to retain residents. They further control activities consuming land in the urban fringe to prevent urban sprawl and to direct land development to the inner parts. The spatial focus of planning strategies for shrinking cities in Germany, for example, is diverse: Formal strategies are implemented at different administrative levels, that is, municipalities, the city, regions, and the federal state. Informal

strategies are frequently implemented at an intermediate level – larger than municipalities and smaller than regions. The same applies to inter-municipal cooperation, which, by definition, refers to aggregates of municipalities. There is a "gap" regarding formal planning strategies at the level of the urban landscape, which implies that well-rehearsed forms of decision-making by state actors are not prevalent here [67]. In addition to formal planning, governance – equal voice for all participants in decision-making – plays an increasing role for informal spatial planning [68], also and predominantly in urban regions. However, a sustainable future of a shrinking city can only be ensured through shared policies and planning that also involves the land owners and local entrepreneurs. Sustainable development of settlements also demands the expansion of regional cooperation across city boundaries. Wherever there are cities with excess vacant land, local entrepreneurs will attempt to extract value from such vacancy. However, local regulations, liability concerns, and the objections of nearby landowners prevent them from pursuing innovative temporary uses [2].

Shrinking cities have a range of opportunities to adapt their planning, also at very limited financial budgets: Outsourcing of urban green space maintenance, development of a more heterogeneous green network including a new complexity and disorder and the permission of more natural development. It is their chance to bring (less) people closer to nature and to involve private land owners into such programs. Strategies for integrated rural–urban development play an increasingly important role besides classic instruments, such as spatial development plans and zoning [69]. New media and formats such as planning games might facilitate an urban region's process of collectively tackling shrinkage. Models and scenarios make it easier to recognize and estimate land use potential and risks of shrinkage at an early stage [69], but they need to be accepted as communication platform by all participants, particularly local and regional stakeholders [70].

Ways of Implementation – The Pilot Case of Eastern Germany

Creating realistic visions for shrinkage is the main planning approach in eastern Germany, sponsored by the federal funding program "Urban Renewal East" (*in German* "Stadtumbau Ost"), which began in 2001 [2]. As consequence of the population decline, first of all the massive out-migration of the 1990s, eastern German cities are faced with emptying and devastated housing areas, unused infrastructure, and pattern of perforation. Urban policy makers are needed to find solutions to counteract the decline of the urban fabric and, what is more, to create urban livelihoods that "accept" shrinkage and partial vacancies as long-term phenomena. Thus, in the mid-1990s, planners started to talk about urban reconstruction and renewal realizing that prevailing urban structures did not meet the needs of a shrinking development (Fig. 10).

In this context, a set of nationally funded regeneration programs had been developed (Fig. 10): Whereas at the beginning of the 1990s "classical" programs, such as the Federal Program of Urban Renewal or WENG (a program dedicated to enhance the development of prefab housing estates) focusing on an encompassing approach of urban regeneration dominated, the situation changed after having supported the reconstruction of major parts of the eastern German core cities. The problem of a simultaneous emptying of the housing stock remained. Thus, in the late 1990s, reconstructed, old built-up housing estates were as same affected with vacancy as GDR-time prefabricated blocks.

In a second phase, urban planners initiated several new programs to find answers on this urban decline. Accordingly, "integrated programs" as a new approach in urban regeneration focusing not exclusively on the urban fabric but also on social, economic, and ecologic aspects were implemented. A couple of years ago, in 1999, the program "Social City" (*in German* Soziale Stadt) came into action foreseen to counteract the increasing social and spatial segregation as well as results of urban shrinkage and abandonment within eastern German cities. Currently, this program supports 390 initiatives in 260 German cities (www.sozialestadt.de; Fig. 10).

Set against this well-developed planning background for urban areas in the Germany after reunification, it became however clear that urban shrinkage needs specific interventions such as e.g., the opportunity of massive demolition in order to be regulated or steered (www.exwost.de). Consequently, in particular for the eastern part of Germany the intervention program "Urban Renewal East" had been

Landscape Planning/Design of Shrinking Landscapes. Figure 10
Spatial and landscape planning repertoire of Germany with respect to urban shrinkage and renewal. SEKo is the new integrated urban development plan for the city of Leipzig that acknowledges simultaneous shrinkage and growth processes

implemented in 2002. To be primarily a reaction on the enormous vacancy rates the urban renewal program predominantly focused on the consolidation of the housing market aiming at a balance between housing demand and supply which is nevertheless until recently not really given: in many districts of cities like Leipzig, Chemnitz, Zwickau, Halle, or Magdeburg, the supply of dwellings outweighs the demand by far. To support the municipal housing cooperatives as well as the private house owners being economically weakened by such high vacancies is a central goal of "Urban Renewal East." In doing so, it focuses on either up-valuation of neighborhoods or on dilapidation of vacant buildings (Fig. 10).

In this vein, three different strategies had been implemented in the city of Leipzig by urban administration: one to foster urban regeneration, the already mentioned initiative "Social City" based on a manifold scenery of subsidies and, the two European programs "URBAN II" and "EFRE" came to action but these are per se spatially up-divided across the urban area of Leipzig. Thus "URBAN II" focuses on the regeneration of the western part of the city being characterized by large housing estates of the Wilhelminian style, devastated factory buildings, and large brownfields. Activities of "EFRE" and the "Social City" support urban regeneration in the eastern part of the city. In terms of urban environment, ecology, and local livelihoods, both programs fund mainly actions to improve the urban quality of life, to assist in cultural and social beliefs, and support medium and small enterprises (Fig. 10). Recently, these strategies found entrance in the new integrated urban development plan SEKo, which had been established in 2009 and covers the entire city area.

Temporary Use of Brownfields – An Innovative City Intervention Strategy

As [2] argue, less regulation and more help for grassroots experimentation may provide large new opportunities for urban regeneration in shrinking cities.

One example is the temporary or interim use of vacant plots. Though temporary or interim use is not completely new (Berlin's Tiergarten after WWII, the 1st community gardens of Los Angeles, etc.), it was first employed as a formal city development strategy in the late 1990s in Germany [71]. Interim land use strategies are extolled as a cost-effective solution to fight urban blight and shrinkage. As examples in Leipzig, Berlin, and Basel have shown, interim uses have the potential to improve esthetics and perceptions of run-down areas, to increase the amount and diversity of green space opportunities and pedestrian routes, and to create new spaces for creative play and performance [71, 72], but they also have the potential to improve the environmental condition of vacant lots.

Perhaps because Leipzig was "the capital of housing vacancies" [73], it was one of the first East German cities to reorient its planning policy to confront shrinkage [3], and it did this with new district development plans, criteria for intervention intensities and priorities, innovative presentation forms, and marketing – "the perforated city" [34] and "more green, less density, greater individuality" [74] – and new planning tools like interim use.

Vacant plots of land growing wild with "weeds" are not pleasant to view for most people and contribute to negative images of neighborhoods. The situation in Leipzig was complicated by the fact that 80% of the vacant buildings and lots belong to private owners, 90% of whom live outside the city; this meant that the city had very few means with which to improve the situation [75].

Improvement of these infill sites necessitated some kind of authorization for property use. Since city acquisition of the plots could only be made in very special circumstances because of the strained municipal budget, and since expropriation is politically unpopular and in any case only possible in exceptional situations, an "authorization agreement" (*in German* Gestattungsvereinbarung) was developed as an informal planning tool to regulate limited term public use of private property while still maintaining the owner's building rights [76]. Advantages for the city include the activation of new green space for public use, connecting green space, and an assurance from the owner to ensure site maintenance, thereby improving quality of life and development attractiveness in the neighborhoods. For the owner, advantages include subsidized land clearance and development, property tax exemption for the duration of the contract, and a reduction of some running costs such as sewage or cleanup from vandalism [71].

So far, 134 public interim use agreements have been concluded for 235 plots totaling 165,905 m^2. When compared to the total area of the city's brownfields (1,942 plots totaling more than 7 million square meters), the scale of interim use agreement interventions seems small, but they are concentrated in three main intervention areas of the city, so in these neighborhoods, the impact is visible. At the program's beginning, contract periods could be for as little as 1 year, though the mean was around 8 years [76]. Now, the Saxon Urban Development Regulation has mandated a 10-year minimum contract period in order to ensure worthwhile use of state funds [71]. Despite this new restriction, interest has remained steady. Current owners under interim use contract often renew contracts because of the lack of city growth. In this sense, interim uses are increasingly becoming more permanent in nature. But what potentials and limitations does this strategy have, and how can these be measured suitably, taking into account both social and environmental factors?

[77] found that, first, interim use sites scored higher overall than their main alternative, recently demolished brownfields, especially on social criteria (i.e., accessibility, recreational interest, and use). Second, interim use sites had a much greater usage rate than other site types, especially by men. The most popular uses of interim use sites are to take shortcuts, to relax, to enjoy nature, and to walk dogs. Third, there was a wide consensus of site condition improvement over the last 6 years. Still, the most desired changes on the six sampled interim use sites are for more benches and better maintenance of the site, especially of dog litter. Fourth, most of the respondents did not know about the city's interim use strategy and do not recognize the sites as being a result of city intervention and development. In so far, it can be hypothesized that public acceptance and support for interim use might be strengthened with increased communication about the strategy and its potential as an urban planning

tool [78]. This could also strengthen use by residents and willingness to participate in site development.

Future Directions

Urban shrinkage is an upcoming phenomenon cities and urban regions face, particularly in the developed world. This entry dealt with the drivers, processes, and patterns behind. Discussing the socio-demographic, land use, and ecological dimension of urban shrinkage, the entry showed the problems and threats related to population decline and economic blight. However, concerning sustainability, urban shrinkage also bears potentials and opportunities.

Urban shrinkage could allow a resurgence of nature into inner cities that are densely populated and have been built up "for ages." In this vein, ideas regarding urban wilderness for recreational and educational purposes are of concern among urban planners and landscape architects who are confronting this shrinkage. The eastern German city of Leipzig, quite a model city, has made the novel suggestion of creating urban greenery in the form of temporary green spaces at core city demolition sites as a kind of planned alternative and spontaneous and ruderal nature on former brownfields as a kind of unplanned alternative. Particularly, green spaces developed from inner-city brownfields represent "flagships" or "experimental fields" that serve as models for future greening endeavors to improve both local biodiversity and human livelihoods. Besides total demolition of houses, shrinkage also leads to a deconstruction of multistory housing stock in the form of a transition toward more spacious housing and living conditions in densely urbanized environments: bigger apartments and integrated patios and terraces, as well as higher shares of urban green and landscape within the neighborhood.

Doubtless, there is considerable potential for social, residential, and ecological improvement in shrinking cities, which, through exploring opportunities as discussed above, might attract new residents for a longer period of time and keep local dwellers in the city, instead of having them choose the detached-house alternative. This opens a new pathway to counteract urban sprawl and thus contributing to urban sustainability.

Acknowledgments

I would like to thank the editor-in-chief of the Encyclopedia for Sustainability Science and Technology, Robert A. Meyers, the Springer Editors, namely, Julia Körting, and my colleague Martin Volk for his useful comments on an earlier version of the manuscript.

Antarctic bottom water A dense water mass formed near the Antarctic continental margin that spreads northward to ventilate the abyssal ocean.

Argo floats Autonomous profiling floats that drift with ocean currents at 1–2 km depth and periodically measure temperature and salinity while rising to the sea surface, where the data is transferred by satellite.

Barotropic The depth-independent component of ocean currents. Direct current measurements are needed to determine the barotropic flow.

Baroclinic The depth-dependent component of ocean currents. The baroclinic flow can be estimated from measurements of ocean density.

Deep western boundary current Strong deep flows intensified along the western boundary of the basins.

Eddy The small-scale, time-variable component of the ocean circulation (also mesoscale eddy).

Ekman transport Wind-driven transport of the surface layer of the ocean to the right (left) of the wind in the northern (southern) hemisphere.

Geostrophic flow The large-scale flow of the oceans is in geostrophic balance, where horizontal pressure gradients are balanced by the Coriolis force.

Glider Like an Argo float with wings, an autonomous instrument that varies its buoyancy allowing it to move both vertically and horizontally, measuring water properties.

Hydrographic sections Ship transects along which measurements are made of seawater properties (e.g., temperature, salinity, carbon, nutrients).

Meridional In the north–south direction.

Meridional overturning circulation A basin-integrated view of the net north–south flow in the ocean basins.

North Atlantic deep water Deep water formed in high latitudes of the North Atlantic that spreads to the south in a deep western boundary current.

Ocean conveyor belt A highly simplified conceptual representation of the large-scale overturning circulation of the oceans.

Overturning circulation A global-scale network of ocean currents consisting of sinking of dense water in a small number of deep water formation regions and a compensating return flow of water in the upper ocean.

Potential vorticity A property of a fluid related to its rotation rate and stratification, which is approximately conserved by the large-scale ocean circulation. Analogous to angular momentum.

Sverdrup A unit of the volume of water carried by ocean currents (1 Sv = 10^6 m^3 s^{-1}).

Thermohaline circulation A term sometimes used as a synonym for the overturning circulation, or more specifically the portion of the overturning circulation driven by exchange of heat and moisture (i.e., thermohaline forcing) at the sea surface.

Ventilation The transfer of surface waters to the interior ocean, resulting in renewal of oxygen levels and other properties of the subsurface ocean.

Water mass A volume of the ocean with similar water mass properties.

Water mass formation The process by which surface water acquires a characteristic set of water mass properties through air–sea interaction, and transfers these properties into the ocean interior when the water mass sinks.

Zonal The east–west direction.

Definition of the Subject

Roughly half the world ocean volume lies below 2,000 m depth. This deep half of the ocean is cold (<3°C), indicating that the abyssal ocean is filled with waters that sink in high latitudes, where cold surface waters are found [1]. The deep ocean circulation transports the cold waters that sink in the polar regions throughout the deep ocean basins. The transfer of surface water to the deep ocean must be balanced by an inflow of water in the upper ocean to the deep water formation regions, to conserve mass. The result is an "overturning circulation ," in which the export of cold deep waters from the source regions is balanced by a return flow of warmer water in the upper ocean. The large temperature contrast between the upper and lower limbs of the overturning circulation makes this flow pattern an efficient means of transporting heat. The large-scale overturning circulation is the primary means by which the ocean stores and transports quantities of relevance to the Earth's climate system and biogeochemical cycles, including heat, freshwater, carbon, and nutrients. The evolution of climate is therefore influenced strongly by the overturning circulation.

The deep ocean, once thought to be largely quiescent, is now recognized to include energetic flows in many locations. The classical description of the deep ocean circulation includes deep boundary currents along the western boundaries of ocean basins, and quieter flows in the ocean interior. Observations from long-term moorings and deep floats have illustrated a more dynamic deep ocean environment, with energetic variability observed at a wide range of space and timescales, including narrow jets, eddies, and recirculating gyres.

The deep and overturning circulations are difficult to observe with existing tools. Most of the knowledge of deep currents has been inferred from the distribution of properties measured along hydrographic transects occupied by ships. The coverage of the deep ocean by full-depth hydrographic sections remains sparse in space and time. In addition, the property distributions reflect the integrated response to a combination of advective and diffusive processes and their interpretation in terms of deep circulation can be ambiguous. Direct measurements of deep currents, for example from current meter moorings, are even less common. The deep ocean circulation, therefore, remains largely unobserved. However, new tools are now making it feasible to obtain sustained measurements of the deep ocean.

Introduction

The conceptual framework developed by Stommel [2] still guides present thinking about the nature of the deep ocean circulation. Deep water that sinks in the polar regions of the ocean must flow away from the source regions. Stommel recognized that on a rotating earth these deep currents will be intensified along the western boundary of the ocean basins, forming "deep western boundary currents" (DWBCs). The sinking in the deep water formation regions was presumed to be balanced by weak upwelling distributed uniformly over the rest of the global ocean. The "stretching" of water columns produced by this upwelling requires that fluid must move poleward in the ocean interior to conserve potential vorticity. Stommel and Arons [3, 4] used these concepts to map the expected circulation pattern in the deep ocean, consisting of concentrated deep flows along the boundary of each basin and weak poleward flow in the interior (Fig. 1).

Both the upwelling and the interior flow are too weak to measure directly. Efforts to test this model of the deep circulation have therefore focused on measurements of the deep western boundary currents [5]. Swallow and Worthington [6, 7] used neutrally buoyant floats to confirm the presence of a deep southward flow along the western boundary of the North Atlantic. Warren and others used measurements of water properties collected by ships and direct velocity measurements from current meter moorings to identify DWBCs in each of the ocean basins [8–10]. In particular, the fact that the DWBCs carry waters that have recently been in contact with the atmosphere, and hence are rich in gases like oxygen and chlorofluorocarbons, means that tracer measurements provide a powerful tool for mapping the deep circulation.

In the modern ocean, deep water is only formed in a few locations in the high-latitude North Atlantic and over the Antarctic continental shelf. The density of seawater depends on both temperature and salinity. To sink from the sea surface to the deep ocean, surface

Large-Scale Ocean Circulation: Deep Circulation and Meridional Overturning. Figure 1
The abyssal circulation according to Stomme's model [2]. Sources of deep water in the northern North Atlantic and Antarctica are denoted by *black dots*. These water masses are carried away from the source regions by a network of deep western boundary currents that feed weak poleward flows in the interior of each ocean basin (Reprinted from [4], as modified by [56], with permission)

waters must become sufficiently cold and salty to be denser than the water below. The surface waters in the high-latitude North Pacific are so fresh that even when cooled to the freezing point, they remain too buoyant to sink [11]. Even in the North Atlantic and the Southern Ocean, deep water is only formed in a few particular regions where air-sea heat loss and the release of brine during sea ice formation result in a sufficient increase in density to cause surface waters to sink.

The flow of deep water away from the source regions is balanced by a return flow of warmer, lighter water in the upper ocean. These counter flows, linked by formation of dense water at high latitude, form an overturning cell. The northward transport of warm water in the upper ocean and compensating southward transport of cold water at depth results in a poleward transport of heat in the Atlantic basin. The large temperature contrast between the upper and lower limb of the overturning makes this circulation pattern an efficient means of transporting heat. In fact, at midlatitudes the ocean and atmosphere make roughly equal contributions to the poleward redistribution of heat absorbed in the tropical regions. The overturning circulation is also an important player in the biogeochemical cycles of carbon, nutrients, and other properties.

Various terms have been used to refer to the overturning circulation . Because deep water formation depends on density, and hence on temperature and salinity, the circulation is often referred to as the thermohaline circulation. However, as discussed below, it is not clear that the overturning is driven solely or primarily by the exchange of heat and moisture and so the term "thermohaline" is potentially misleading. In addition, the phrase has been used by many authors to mean different things, adding to the confusion [12].

In the Atlantic, the term "meridional overturning circulation (MOC)" is commonly used. However, the global-scale overturning circulation involves zonal as well as meridional flows, and the zonally averaged perspective inherent in the term MOC is itself potentially misleading. Therefore, the more general term overturning circulation is used here.

Another term, the "great ocean conveyor belt," was introduced by Wally Broecker [13, 14]. He highlighted the link between glacial cycles and variations in the strength of the overturning circulation. In particular, the addition of freshwater from melting continental ice sheets during the transition from glacial to interglacial conditions made surface waters in the North Atlantic too buoyant to sink, slowing the heat transport by the ocean conveyor, and cooling northern hemisphere climate. The switching on and off of the conveyor was linked to temperature changes in Greenland as large as 10°C over periods as short as a decade or two. Broecker's work highlighted the role of the "ocean conveyor" in global climate and renewed interest in the forcing of the circulation and its sensitivity to changes in forcing (in particular, freshwater input).

Broecker's "conveyor belt" picture was intended to serve as a logo or metaphor for the much more complex, three-dimensional, and time-variable circulation now commonly referred to as the overturning circulation, rather than as a realistic depiction of the flow. The actual flow paths involved in the global overturning circulation are much more complex, including narrow boundary currents, recirculation gyres, small-scale eddies, and jets. The deep circulation is steered by the topography of the seafloor and can also be influenced by the deep expression of circulation features in the upper ocean, such as boundary currents and eddies.

The large capacity of the ocean to store heat has a significant influence on climate. For example, more than 93% of the extra heat energy stored by the Earth system over the last 50 years is found in the ocean [15, 16]. The extra heat stored in the ocean has caused a rise in sea level, as a consequence of thermal expansion of the water column. Most of the extra heat stored in the ocean has accumulated in the upper 700 m. However, there is increasing recognition that the deep ocean makes a significant contribution to ocean heat storage and sea-level rise [17]. Accounting for the contribution of the deep ocean is necessary to explain the observed record of past sea-level rise (e.g., [18]) and to close the overall energy budget of the earth [17]. In addition, the warming projected by climate models for a given level of greenhouse gas forcing (called the climate sensitivity) is sensitive to the amount and depth of ocean heat storage [19]. Observations of the deep ocean are therefore needed to improve climate projections and to understand changes in sea level and the planetary energy budget.

Progress in understanding the deep circulation has been slowed by the technical challenge of observing the deep ocean. While new instruments like Argo profiling floats have revolutionized the ability to observe the upper 2 km of the ocean, providing the first year-round, broad-scale measurements of the ocean, no equivalent yet exists for the deep ocean. Deep ocean observing systems still rely heavily on traditional oceanographic platforms like ships and moorings. Because research vessels and long-term deep water moorings are expensive, the spatial and temporal coverage of deep ocean observations remains very limited. The deep ocean is now recognized to be more energetic and to include flows on smaller spatial scales than once believed, characteristics that increase the challenge of observing the deep circulation and its variability.

Deep Water Masses and Circulation

Sources of Deep and Bottom Water

To sink from the sea surface to the deep ocean, surface waters must become sufficiently dense, hence cold and/or salty. These conditions are met in only a handful of places in the present day ocean. Warm, saline waters move north in the upper layers of the Atlantic Ocean, gradually losing heat to the atmosphere, until ultimately sinking in the Norwegian, Greenland, and Iceland seas. These dense waters spill through gaps in the ridge system isolating the northern seas from the North Atlantic. Mixing with ambient waters during the descent into the deep North Atlantic increases the volume and modifies the properties of the dense overflows. Deep convection in the Labrador Sea produces somewhat lighter and warmer water which contributes to the deep waters in the basin. Collectively these dense waters supplied to the basin are known as North Atlantic Deep Water (NADW).

An even denser water mass, known as Antarctic Bottom Water (AABW), is formed in several locations around the margin of Antarctica. Heat lost to the atmosphere cools the ocean and, if the sea temperature reaches the freezing point of about −1.8°C, results in the formation of sea ice. Salty brine released when sea ice forms increases the density of the underlying water and makes an important contribution to the formation of dense shelf waters. As the dense waters flow off the shelf and sink into the deep ocean, they entrain about three times their volume of ambient waters [20]. The mixture of dense shelf waters and entrained fluid forms AABW. The primary sources of AABW are the Weddell Sea in the Atlantic sector, the Ross Sea in the Pacific sector, and the Adélie/Wilkes Land coast south of Australia [20–22].

NADW and AABW are examples of water masses, volumes of water with similar physical and chemical properties, reflecting a common origin. Water masses acquire their characteristic properties (e.g., temperature, salinity, and dissolved gas concentrations) through exchange between the surface ocean and the atmosphere. When water masses sink from the sea surface, they carry these characteristic properties with them into the ocean interior. These properties gradually evolve as the water masses are carried away from the source regions by ocean currents, as a result of mixing with water masses with different characteristics, but mixing is relatively weak in the ocean and water mass properties tend to be retained for long distances. Maps of water properties can thus be used to trace the spreading paths of water masses. In fact, given the difficulty of directly observing deep ocean currents, much of what is known about the deep circulation has been inferred from the distribution of water mass properties.

For example, surface waters in contact with the atmosphere are rich in dissolved gases like oxygen and chlorofluorocarbons (CFCs). The distribution of oxygen and CFC reflects the flow paths of deep water away from the source regions. Figure 2 shows the distribution of CFC-11 in the North Atlantic, illustrating the spreading pathway of the recently ventilated North Atlantic Deep Water [23]. At 24°N in the Atlantic, high CFC concentrations are observed in the deep ocean in the western basin, with the highest values observed adjacent to the boundary. A map of the inventory of CFC-11 in the NADW shows a plume of high CFCs spreading southward along the western boundary from the deep water formation regions in the Greenland –Iceland-Norwegian and Labrador Seas (Fig. 2b). Figure 3 shows a similar plot for the Southern Ocean, illustrating the three main sources of Antarctic Bottom Water in the Weddell and Ross Seas and the Adélie/Wilkes Land coast and the system of boundary currents exporting AABW to lower latitudes [20]. As seen in the North Atlantic, the highest concentrations are observed along the western boundary of each ocean basin. NADW and AABW supply roughly equal amounts ($10 - 15 \times 10^6$ m^3 s^{-1}) of dense water to the deep ocean [24] and AABW occupies roughly twice the volume of NADW [25].

No dense water is formed in the northern Indian and Pacific basins. The north Indian Ocean is limited to relatively low latitudes and so strong cooling of the ocean does not occur there. The Pacific extends to high latitudes and enough heat is lost to freeze the sea surface in winter. However, the surface waters of the Pacific are so fresh that even when cooled to the freezing point they are too buoyant to sink into the deep ocean [11]. These basins are therefore ventilated from the south, by a mixture of NADW exported from the Atlantic and AABW formed in the Southern Ocean, called Circumpolar Deep Water (CDW) [26]. This can be seen clearly in the distribution of oxygen in the deep ocean in these basins. High oxygen values spread northward from the Southern Ocean at 4,000 m depth in the Pacific, with the strongest penetration seen to the east of the large bathymetric obstacle imposed by the Tonga–Kermadec Ridge (Fig. 4). Oxygen values are low in the North Pacific and spatial gradients are small, indicating relatively weak flow there. The oxygen distribution at 33°S in the Indian Ocean shows that the lowest oxygen values are observed at mid-depth, sandwiched between the well-ventilated upper ocean waters that have been in recent contact with the atmosphere and relatively oxygen-rich deep waters spreading northward into the basin along the western sides of the deep basins (Fig. 5).

Deep Ocean Circulation

The distribution of water mass properties in the deep ocean reflects the formation and spreading of dense water formed at high latitudes in the North Atlantic and Southern Oceans. More specifically, the property

Large-Scale Ocean Circulation: Deep Circulation and Meridional Overturning. Figure 2

The initials indicate different water masses; *dashed lines* indicate surfaces of constant density. The neutral density surfaces defining the water mass boundaries are plotted as bold *dashed lines*. (**b**) The inventory of CFC-11 (molkm_2) in the density layer corresponding to dense overflow waters exported from the Greenland–Iceland–Norwegian Seas through the Denmark Straits (DSOW) (From [23], used with permission)

Large-Scale Ocean Circulation: Deep Circulation and Meridional Overturning. Figure 3
Inventory of CFC-11 in the Antarctic bottom water layer. High concentrations (*blue*) near the Weddell Sea, Ross Sea, and Adélie/Wilkes Land Coast indicate the three major sources of Antarctic bottom water (Adapted from [20])

distributions indicate the dominant role played by deep western boundary currents in the deep circulation. Maps of deep ocean properties like Figs. 2, 3, 4 also illustrate several other important aspects of the deep circulation: The flow is strongly steered by bathymetric features like the mid-ocean ridges and fracture zones; water properties gradually evolve along the flow path as a result of mixing; and water mass properties often change more abruptly near sills between basins (e.g., the Samoa Passage near 10 S, 175 W, Fig. 4), suggesting enhanced mixing in these regions.

The transport of the deep western boundary currents have been measured at a number of locations in the Atlantic and at a few locations in the Indian and Pacific basins, from long-term moored experiments or hydrographic sections. Hogg [27] provides a useful summary of measurements that existed at that time. A DWBC carrying NADW southward can be identified throughout the Atlantic (e.g., Fig. 2b). AABW and CDW formed from a mixture of AABW and NADW flows northward along the western boundary of most of the deep basins surrounding Antarctica, as seen in Figs. 3 and 5.

Such measurements confirm the existence of the DWBCs expected from the Stommel's theory. However, as observations of the deep ocean have increased in number and duration, it has become clear that the deep circulation is more complex than illustrated

Large-Scale Ocean Circulation: Deep Circulation and Meridional Overturning. Figure 4
Oxygen concentration at 4,000 m depth in the Pacific, illustrating the inflow of relatively oxygen-rich Circumpolar Deep Water in a deep western boundary current to the east of New Zealand. From the WOCE Pacific Atlas; used with permission

in Fig. 1. Energetic eddies are common in the vicinity of the deep boundary currents, produced by dynamical instabilities of the currents. Stable transport estimates therefore require time series of sufficient duration to average over the eddy signal. In addition, momentum fluxes associated with these eddies drive recirculating gyres offshore of many DWBCs (e.g., [28, 29]). The presence of the deep recirculation gyres complicates efforts to measure the net transport of the DWBCs associated with the large-scale overturning circulation: few moored arrays span both the DWBC and the offshore gyres, as required to separate the recirculating and throughflow components of the DWBC.

The weak poleward flow expected from Stommel's deep circulation theory has proven even more elusive to observe. The first attempts to use neutrally bouyant floats to measure the interior flow instead discovered mesoscale eddies [30, 31]. Stommel's theory assumed a flat-bottomed ocean. The presence of seafloor

Large-Scale Ocean Circulation: Deep Circulation and Meridional Overturning. Figure 5
Oxygen concentration at 33°S in the Indian Ocean. Abyssal waters are relatively rich in oxygen, with the highest values seen near the seafloor on the western side of each deep basin, reflecting the presence of deep western boundary currents (From WOCE Pacific Atlas; used with permission)

bathymetry both steers the deep flow and can affect the dynamics of the deep circulation by driving vertical motions near the seafloor and hence meridional motion, analogous to the poleward flow caused by upwelling at the top of the deep layer in the Stommel model. In a basin with realistic bathymetry, therefore, one would not necessarily expect to see uniform poleward flow in the interior. Neutrally buoyant floats were used to study the deep flow in the Brazil Basin during the World Ocean Circulation Experiment [32]. Rather than weak poleward flow, the floats revealed alternating east–west (zonal) flows, with short north–south (meridional) scales, in the interior of the basin. The zonal flows in the interior were interpreted to be consistent with the idea that mixing (and therefore upwelling) was limited to the rough topography around the rim of the basin (as directly observed during the experiment, [33]). With no upwelling in the interior, there is no vortex stretching and no requirement for meridional flow in order to conserve potential vorticity. Zonal flows in the ocean interior have since been observed in many parts of the ocean [34].

Global Overturning Circulation

The DWBCs that dominate the circulation of the deep ocean form the lower limb of the global overturning circulation. To balance the sinking of dense water in the North Atlantic and Southern Ocean, an equal volume of water in the upper ocean must flow toward the sinking regions in the upper limb of the overturning circulation. The shallow and deep branches of the OC must be linked by upwelling (and therefore mixing) somewhere in the ocean interior. While the existence of a global-scale circulation pattern linking the high-latitude sources of deep water to lower latitudes, and the upper layers of the ocean to the deep sea, has been recognized for many years, a quantitative understanding of the structure and dynamics of the overturning circulation was lacking.

Role of the Overturning Circulation in Climate and Biogeochemical Cycles The OC is a primary mechanism for the transport and storage of heat and freshwater and carbon by the ocean and therefore has a substantial impact on climate variability and change [35]. For example, in the North Atlantic the ocean carries about 1×10^{15} W of heat to the north, helping to moderate the climate of western Europe. The relative contribution of deep and shallow overturning cells to the net meridional transport of heat and freshwater varies between the ocean basins [36, 37]. Changes in the OC have been linked to past climate variations, including abrupt changes caused by a slowing of the overturning, and climate models suggest the circulation will both respond to and modulate climate change in the future (e.g., [38]). In particular, large inflows of freshwater produced from melting of ice during the transition out of glacial cycles are believed to have made the surface waters of the North Atlantic so buoyant that dense water was no longer formed [14]. The resulting slowdown of the overturning circulation and reduction in heat transport led to rapid cooling. Climate models project a slowdown of the overturning circulation of about 30% over the next century, as a result of warming and freshening of the surface layers of the ocean, although the magnitude and sensitivity to change of the overturning varies widely between models.

The OC also plays an important role in the global cycles of carbon, nutrients, and other properties. Sinking of organic matter transfers nutrients and carbon from the surface to the deep ocean. Upwelling of deep water as part of the OC, particularly in the Southern Ocean, returns nutrients to the surface ocean to support phytoplankton growth [39]. Models suggest that nutrients upwelled and exported by the Southern Ocean support 75% of global primary production north of 30°S [39]. Changes in the overturning circulation would therefore be expected to influence global primary productivity and ecosystem function [40]. Deep water is also rich in carbon and the efficiency with which the ocean sequesters carbon dioxide from the atmosphere depends on a balance between the outgassing from upwelled deep water and the physical and biological processes acting to transport carbon into the ocean interior [41]. Projections of future climate change are sensitive to the rate of carbon uptake by the ocean in climate models and therefore sensitive to the overturning circulation. Atmospheric observations and coarse-resolution ocean model studies have suggested that the carbon sink in the Southern Ocean has "saturated" in recent decades, as a result of an increase in

strength of the overturning circulation (and hence increased outgassing of natural carbon from the deep ocean) in response to stronger winds [41]. This result, however, may significantly change when ocean eddy feedback processes are resolved [42]. The upwelling of carbon-rich deep water will also affect the carbon saturation state and pH of surface waters, with implications for calcifying organisms and marine ecosystems.

Seasonal and interannual climate variability is largely independent of the deep ocean and OC. But as the timescale of climate variability increases, the deep ocean becomes an increasingly important player. For example, a number of recent studies have shown that sea surface temperature variations on multi-decadal timescales are influenced by the overturning circulation (see [43] for a summary). These multi-decadal anomalies in Atlantic sea surface temperature (SST), known as the Atlantic Multi-decadal Oscillation, have in turn been linked to regional climate anomalies, persistent drought, hurricane frequency, and fisheries production (see [44–46] and references therein). On these timescales, the evolution of climate tends to be dominated by the slow dynamics of the ocean rather than the atmosphere [47, 48], suggesting that it may be possible to exploit ocean information to improve the prediction of these phenomena. For example, advection of salinity anomalies by the OC can result in decadal variability of the OC and its heat transport, and therefore in anomalies of sea surface temperature that drive decadal variability in the overlying atmosphere [45].

Conceptual Models of the Overturning Circulation

Observations of the deep circulation (section Deep Ocean Circulation) reveal features both consistent with (e.g., DWBCs) and at odds with (e.g., lack of evidence of poleward flow in the interior) the simple pattern (Fig. 1) expected from Stommel's model for the deep circulation. The limited deep observations available to date also reveal a variety of small-scale, energetic flows that complicate efforts to observe and understand the overturning. The connections between the upper and lower limbs of the overturning and the nature of the interior flows have been particularly difficult to quantify and understand. Nevertheless, a more complete conceptual model of the overturning circulation has gradually evolved over the past 25 years.

In the absence of other information, Stommel assumed the sinking at high latitudes was balanced by uniform upwelling elsewhere. A consequence of uniform upwelling was that much of the return to the upper ocean must take place in the Pacific, the largest ocean basin. There must therefore be exchange pathways in the upper ocean to return fluid upwelled in the Pacific and Indian Oceans to the Atlantic to complete the loop. Broecker and Peng [49] were the first to refer to the resulting global circulation pattern as a "conveyor belt" and to attempt to illustrate the circulation with a two-layer schematic. Gordon's [50] version of this schematic included a more realistic representation of the regional currents and interbasin exchanges involved in the global cell, and was the first to include estimates of the transports carried by the various branches. A visually compelling cartoon of the two-layer schematic published by Broecker [13] with the title "Great Ocean Conveyor Belt" grabbed the imagination of many and was used in Broecker [14] to illustrate the role of the overturning circulation in glacial–interglacial cycles. Figure 6 shows a version of the Broecker conveyor belt, modified to include the Antarctic sources of deep water and the interbasin connection provided by the Antarctic Circumpolar Current.

A series of authors have sought to add to the realism of Broecker's schematic diagram, while retaining the power of a simple representation of the flow. Richardson [51] provides a very useful overview of the history of such diagrams. Here a few of the major contributions are highlighted. Gordon ([52]; figure reproduced in [51]) used a novel three-dimensional representation of the oceans to represent the global nature of the overturning circulation, including the major interbasin exchanges, alternating flows at different depths in each basin, and the upwelling and mixing that link the upper and lower limbs. Schmitz [53, 54] revised and colored Gordon's scheme. Lumpkin and Speer [55] (Fig. 7) further revised this schematic and added estimates of the transport of the major current branches.

Several authors have refined two-dimensional schematics of the overturning. In particular, the reports by Schmitz [53, 54] include a number of multilayer pictures of the global overturning, an example of which is shown in Fig. 8. These schematics were constructed by

Large-Scale Ocean Circulation: Deep Circulation and Meridional Overturning. Figure 6

summarizing the results of a large number of regional and global studies and are particularly notable because they are quantitative, with an internally consistent set of transport estimates provided for each branch of the circulation. Finally, the schematic of Lumpkin (modified by Speich, 2009, personal communication) is a recent attempt to convey the global overturning in a more realistic fashion, including the major pathways, recirculating gyres, interbasin exchanges, water mass transformations, and eddies (Fig. 9).

A number of recent results have called aspects of the "conveyor belt" view of the overturning circulation into question [56]. The fact that an overturning circulation exists in the ocean is clearly supported by ocean observations, model studies and theory. However, it is becoming increasingly clear that it is inappropriate to think of this flow as a continuous, steady "belt" of flow connecting the ocean basins. (This was of course obvious from the start to the authors of early schematics of the overturning circulation, but the conveyor belt metaphor has at times been interpreted more literally than intended, perhaps a victim of its own success.) For example, the DWBC in the Atlantic is apparently not as continuous as once believed [57]. Eddies detrain and re-entrain fluid into the boundary current and into recirculation gyres, diluting waters in the boundary current and spreading the flow over a larger fraction of the interior of the basin. Floats have also revealed the importance of interior pathways [58]. The fact that local, time-varying processes (e.g., wind forcing, eddies, and recirculation gyres) can influence the transport of the DWBC means that variations in the strength of the current with time, or with latitude, do not provide an unambiguous indication of changes in the production of dense water in the source regions, as once assumed [56]. Moreover, evidence is growing that both the upper and lower limbs of the overturning are sensitive to wind and buoyancy forcing and to mixing. For example, it is not clear whether it is more appropriate to think of the overturning circulation as "pushed" by formation of dense water or "pulled" by upwelling driven by winds in the Southern Ocean and by vertical mixing [59]. Attribution of the cause of changes in the overturning is difficult because

variations may reflect the response to a range of physical processes (e.g., eddies and wind) in addition to buoyancy forcing at high latitudes, as believed when the "conveyor belt" concept was developed.

Observations of the Overturning Circulation The transport of properties by the OC depends on the rate of overturning and the difference in property concentration between the upper and lower limbs of the overturning; in many locations, the horizontal gyres also contribute to the meridional transport of heat and other properties. Therefore observations of the property transport by the OC must extend throughout the full depth and breadth of the ocean basins. With present technology, this is generally not feasible because of the expense of deploying a coherent array of current meter moorings across vast regions of the ocean. However, while continuous, direct measurements of the global OC are not yet possible, new approaches have been developed to allow monitoring of the OC at particular locations. An important achievement in the last decade is the first multiyear time series of the meridional mass transport contributing to the overturning circulation in the Atlantic sector.

For example, an array of instruments has been deployed to measure the overturning circulation crossing 26.5°N in the Atlantic [60–62]. Figure 9 shows a 3.5 year time series of the transport of individual components of the OC: the Gulf Stream at Florida Straits, the interior flow in the upper ocean, and the Ekman transport. The mean overturning is 18.5 Sv (1 Sv = 10^6 m^3 s^{-1}), with a standard deviation of 4.9 Sv and a standard error of 1.5 Sv. The fact that the sum of the individual components approximately conserves mass provides additional confidence that the transport estimates are robust [62]. The measurements reveal significant high-frequency variability of the OC on several timescales, underscoring the need for both continuous sampling to avoid aliasing and

Large-Scale Ocean Circulation: Deep Circulation and Meridional Overturning. Figure 8
A three-layer schematic of the global interbasin circulation by Schmitz [54]. Values in circles represent transport in Sverdrups. UPOCNW designates upper ocean water, a combination of upper layer water and intermediate water (From [54]; used with permission)

for long time series to detect trends. The continuous time series is providing new insights into the dynamics of the OC, including identification of the mechanisms responsible for variability of the OC on different timescales (e.g., [63]).

The 26.5°N array exploits the fact that the net geostrophic transport between two points on a latitude circle can be determined from measurements of the pressure difference between the two points. Therefore the volume transport in the interior can be estimated from measurements on either side of the basin, without the need for a coherent array of instruments spanning the basin. This works well at 26.5 N in the Atlantic because of the particular geometry of the basin there. The strong flows in the boundary currents over the continental slope on the western side of the basin need to be measured directly.

The end-point monitoring approach has also proved effective at 16°N in the Atlantic, where the time series of North Atlantic Deep Water export is now more than 9 years long [64, 65]. Flows in the eastern basin contribute little to the net transport. The near-rectangular geometry of the western Atlantic basin allows the OC to be monitored with a small number of instruments and thus is very cost-effective. As found at 26.5°N, the transport of the lower limb of the OC is highly variable on short timescales (Fig. 10). Despite the large high-frequency variability, the time series is of sufficient duration to detect a weakening trend (significant at 85%), corresponding to a 3 Sv reduction in the NADW export over the duration of the record.

The demonstration that continuous measurements of the basin-scale overturning circulation can be made using a small number of instruments is a remarkable achievement. However, the subtropical North Atlantic represents a special case where the near-rectangular geometry of the ocean basins means that the end-point

Large-Scale Ocean Circulation: Deep Circulation and Meridional Overturning. Figure 9
Transport of the overturning circulation at 24 N in the Atlantic. Gulf Stream transport through the Florida Straits (*blue*), Ekman transport (*black*), upper mid-ocean transport (*magenta*), and overturning transport (*red*). Transports in Sv, positive northward. Florida Straits transport is based on electromagnetic cable measurements. Ekman transport is based on scatterometer winds. The upper mid-ocean transport is the vertical integral of the transport per unit depth down to 1,100 m. Overturning transport is the sum of Florida Straits, Ekman, and upper mid-ocean transport. The mean $\pm$ standard deviation of Gulf Stream, Ekman, upper-mid ocean, and overturning transports are 31.7 $\pm$ 2.8 Sv, 3.5 $\pm$ 3.4 Sv, -16.6 ± 3.2 Sv, and 18.5 $\pm$ 4.9 Sv, respectively (From [61]; used with permission)

monitoring approach can capture most of the flow. Array design studies using general circulation models [66, 67] have identified some of the requirements for a basin-scale observing system for the overturning circulation. Where barotropic flows make a significant contribution to the mass and heat transport, they need to be measured directly and cannot be inferred from observations at the end points of a section. Where western boundary currents are broad (e.g., over sloping topography), extensive, and expensive, moored arrays may be required to resolve them. Complex bathymetry and barotropic flows in the ocean interior also need to be resolved, for example at subpolar latitudes where the gyre circulation makes a significant contribution to the net heat flux. For accurate estimates of property transports, these measurements need to be horizontally coherent to capture the correlations of velocity and temperature that are responsible for heat transport. In other words, at most latitudes, direct observations of the overturning circulation require massive moored arrays that are not feasible with present technology and resources.

While basin integrals of the OC are not yet feasible at most latitudes, major currents contributing to the overturning circulation have now been measured at several locations, in particular in the dense overflows and along the deep western boundary current carrying NADW southward [60, 68, 69]. These measurements have generally spanned the overflow or deep western boundary current, but not the flows in the interior of the basin. The presence of recirculation gyres offshore of the DWBC, usually not resolved by the moored arrays, often makes it difficult to use these measurements to infer the overall strength (or throughflow) of

the OC [69]. However, they do provide robust estimates of a primary pathway of the deep limb of the overturning. The DWBC estimates can be combined with measurements in the ocean interior (e.g., from hydrographic sections) to estimate the OC and net meridional transport. They also provide valuable constraints for ocean state estimates and for the testing of ocean models.

Some current measurements have been made of the DWBC systems in the Indian and Pacific, but they are typically of less than 2-years duration and often lack the supplementary information needed to estimate the basin-wide overturning. As a consequence, estimates of the strength of the OC in the other ocean basins vary over a wide range (e.g., [70–73]). Examples of DWBC measurements include the flows carrying Antarctic Bottom Water (AABW) northward adjacent to the Kerguelen Plateau [74], into the Argentine Basin [75], through the Vema Channel to the Brazil Basin [76], and crossing the equator to enter the North Atlantic [77]; the flow entering the Indian Ocean through the Madagascar [78] and Perth Basins [79]; and the Pacific DWBC at 30°S [80], the Samoa Passage [81] and at 5°N [82].

Observations of Change in the Deep Ocean In climate models, deep ocean heat uptake has been found to be well correlated with the climate sensitivity of the model, with greater ocean heat uptake implying a larger commitment to future warming and sea-level rise [83, 84]. In fact, the degree to which the deep ocean takes up heat may be the largest uncertainty in determining climate sensitivity [19]. A similar argument applies to the ocean uptake of carbon dioxide.

Hence deep ocean measurements are central to reducing uncertainty in projections of global warming and sea-level rise. Observations suggest that warming of the deep ocean has contributed about 20% of the total increase in ocean heat content over the last decade or so [17].

While time series measurements are sparse in the deep ocean, there is increasing evidence of changes in properties and circulation. For example, the Antarctic Bottom Water (AABW) exported from the Southern Ocean to ventilate the abyss of each ocean basin has warmed in recent decades [17, 85–90] (Fig. 11). The changes in deep ocean temperature are sufficient to account for a significant fraction of the global energy imbalance [16, 18, 72, 87]. Reference [17] has estimated that the warming below 4,000 m depth and below 1,000 m south of the Subantarctic Front contributes about 0.09 W m^{-2} to the global heat budget (compared to 0.5 ± 0.18 W m^{-2} for the 0–700 m layer of the ocean [91]). This contribution to the planetary energy budget will grow in importance as the anthropogenic warming signal propagates to increasing depth with time. The warming below 4,000 m contributes about 0.1 mm $year^{-1}$ to global sea-level rise, while the warming below 1,000 m in the Southern Ocean contributes about 1 mm $year^{-1}$ of sea-level rise there. These new studies complement previous results [16, 92, 93], indicating significant warming between 700 and 3,000 m in the North Atlantic Ocean. The dynamical mechanism responsible for the observed abyssal warming is not yet known, but a recent study has highlighted the importance of wave-like motions that can rapidly transfer anomalies over large distances [94]. In this case, the warming of the deep North Pacific was traced back to changes in air-sea heat exchange at the sea surface off the coast of Antarctica, south of Australia.

The possibility that increased freshwater input to the high latitude ocean could cause a slowing of the thermohaline circulation and changes in climate has focused considerable interest on the high-latitude freshwater budget. Changes in upper ocean salinity have been observed in each of the ocean basins, with an increase in salinity in the subtropical evaporation zones and a decrease at higher latitudes that is consistent with a more vigorous hydrological

Large-Scale Ocean Circulation: Deep Circulation and Meridional Overturning. Figure 11

Basin boundaries (*thick gray lines*) and 4000 m isobaths (*thin gray lines*) are shown. The local contribution to the heat flux through 1,000 m south of the SAF (*maroon line*) implied by deep Southern Ocean warming from 1,000 to 4,000 m is also given (*maroon number*) with its 95% confidence interval (From [17]; used with permission)

cycle and increased supply of meltwater at high latitudes [91, 95–97]. Numerous studies documented a freshening of North Atlantic Deep Water between the mid-1960s and the mid-1990s, when an atmospheric circulation pattern known as the North Atlantic Oscillation (NAO) evolved to an extreme positive state (e.g., [98]). The freshening reversed in the mid-1990s. Weakening of westerly winds in the mid-1990s to mid-2000s caused a reduction of deep convection in the Labrador Sea, a slowing and contraction of the subpolar gyre, and a northward advance of warm saline subtropical waters [99–104]. The NAO-induced upper ocean changes were rapidly transferred to deeper levels, causing an increase in temperature and salinity of deep waters [105–107].

While measurements are sparse in the Southern Ocean, several recent studies have detected changes in the salinity of Antarctic Bottom Water [86, 108–112]. The Ross Sea and Adélie Land regions supply about 40% of the total input of AABW [21]. Most of the AABW exported from both sources passes through the Australian Antarctic Basin, making it a good place to monitor changes in properties of the AABW formed in the Indian and Pacific sectors. The deep temperature–salinity relationship has changed throughout the basin in recent decades, with a shift toward fresher and lighter bottom water observed in the deepest 1,000 m of the water column [113]. References [110, 114, 115] suggest that the most likely source of the additional freshwater is basal melt of glacial ice in the Pacific sector. Enhanced basal melting there has been linked to warmer ocean temperatures [116]. In contrast, in the Weddell Sea the situation is ambiguous, with freshening of bottom water in the west [117] and a slight increase in the salinity of deep water in the east [89].

The evidence from the North Atlantic and the Southern Ocean suggests that the dense water sinking in both hemispheres responds to changes in the high latitude freshwater balance, and rapidly transmits this climate signal to the deep ocean. However, in only a few places are the observations sufficiently frequent to avoid aliasing of interannual variability. Expanded arrays of continuous measurements of deep ocean properties are needed to better understand the OC and its response to changes in forcing.

An Observing System for the Deep Ocean and Overturning Circulation

Measuring the OC poses a significant challenge. The OC extends throughout the global ocean, reaches from the sea surface to the sea floor, and consists of both intense narrow boundary currents and broad flows in the ocean interior. In essence, measuring the OC and associated heat and freshwater transport requires observations of the global, full-depth, three-dimensional, time-varying flow of the ocean. The tools to do this do not yet exist. Indeed, the deep ocean remains essentially unmeasured by the present ocean observing system, at least in a continuous sense. Nevertheless, substantial progress has been made in recent years, as discussed above. Building on this foundation, the international community recently developed a strategy for sustained observations of the deep ocean and overturning circulation [118], in the context of a decadal review of the status and prospects for global ocean observations known as OceanObs09 [119, 120]. In the following, the strategy for deep ocean observations developed by that community effort is summarized.

Building Blocks for an Observing System for the OC and Deep Ocean

An observing system for the transport of the OC and deep currents needs to rely on a combination of approaches. For some science questions (e.g., quantifying the transport of the OC), focused arrays of instruments are needed in key pathways of the circulation; for others (e.g., quantifying ocean heat content and its contribution to sea-level rise), broad-scale measurements are needed to track the evolving inventory of climate-relevant variables. In this section, the tools available for sampling the transport and inventory of the deep ocean are described; the following section outlines an initial strategy for their deployment.

Much of the transport of the OC is carried in narrow boundary currents and therefore direct velocity measurements are needed there. Both the surface-intensified but deep-reaching western boundary currents of the subtropical and subpolar gyres, and the deep western boundary currents that dominate the abyssal flow need to be measured. Boundary current transports can be observed using current meter arrays

incorporating point measurements and profiling instruments (e.g., acoustic Doppler current profilers (ADCPs)), cables, pressure gauges, and C-PIES (an Inverted Echo Sounder ((IES)) equipped with a pressure sensor (P) and a current meter (C); the combination provides a cost-effective means of monitoring the ocean, especially in the vicinity of strong currents [121]).

The full-depth volume transport in the interior of deep basins can be inferred from deep hydrographic measurements near the end points (from moorings, ships, gliders, or in some cases C-PIES), using the geostrophic relationship, supplemented by additional measurements over the sloping topography at the basin boundaries or mid-ocean ridges. Estimates of the transport of other properties (e.g., heat, freshwater, carbon), on the other hand, require knowledge of the covariance between velocity and concentration and cannot, in general, be made from end-point measurements alone. Given the prohibitive cost of a coherent "picket fence" of tall moorings spanning ocean basins (and the lack of moored sensors for some properties of interest), repeat hydrographic sections are in most cases the only approach available for estimating property fluxes over the full ocean depth. In some locations, where a close relationship exists between an integral property (e.g., acoustic travel time) and a single mode of variability of vertical profiles of temperature and salinity, property fluxes can be measured using a coherent array of C-PIES.

While the main focus of the entry is on the deep ocean, the OC of course includes flows in the upper ocean as well. To measure the OC, measurements of boundary currents and interior flows in the upper ocean are needed, including the wind-driven Ekman transport in the surface layer. Strategies for measuring the upper ocean are summarized in [119, 120].

Measurements of the evolving inventory of heat, freshwater, carbon, and other properties rely heavily on deep repeat hydrography [122]. Hydrographic sections remain the only tool available to sample the deep ocean over broad scales and the only way to collect samples for biological and biogeochemical analyses. The signal of change will appear first and be most prominent near the dense water overflows and along the main pathways of the deep circulation; hence these areas need to be sampled more frequently. Moored instruments provide the only means to obtain continuous time series of ocean currents and water properties and are therefore a key part of the armory, despite their relatively high cost and therefore limited spatial distribution. Repeat glider transects can also contribute to this goal. Remote sensing from satellites (e.g., altimetry and gravity measurements) or by acoustic means (e.g., acoustic tomography and thermometry) can provide integral constraints on ocean heat content [123]. However, each of these tools has limitations and as a result, changes in full-depth ocean heat content and other properties over most of the ocean can still not be measured accurately.

Because the reliance is on a variety of incomplete or indirect measurements to observe the overturning circulation and deep currents, analysis approaches such as inverse methods or state estimation are often required to combine the observations in a dynamically consistent manner and to interpolate between sparse observations.

A Strategy for a Deep Ocean Observing System

An initial strategy for sustained observations of the OC and deep ocean was articulated by Rintoul et al. [118] and is summarized here and in Fig. 12. For further detail, see [118] and references therein.

To understand the response of the OC and associated property transports to changes in forcing, measurements are needed at several latitudes to allow the meridional coherence of the OC to be assessed and understood. The partitioning of the meridional heat transport between the overturning and horizontal gyre circulations, for example, differs strongly with latitude [124]. Model studies suggest that the meridional coherence of the AOC has different timescales at different latitudes, with stronger decadal variability in the subpolar regime and stronger high-frequency variability in the subtropics [125, 126]. Other model studies suggest that measurements at a single latitude in each basin of the Atlantic might be sufficient to detect OC changes on multidecadal scales, but that measurements at additional latitudes are needed to capture interannual to decadal variability and to understand the role that interocean and interbasin exchanges play in the OC and climate [124, 127].

Basin-wide monitoring of the Atlantic OC and meridional heat and freshwater transport is therefore

Large-Scale Ocean Circulation: Deep Circulation and Meridional Overturning. Figure 12
Schematic of the global ocean overturning circulation. *Red* indicates upper ocean flow, *blue* and *purple* are deep flows, and *yellows* and *greens* represent transitions between depths. The proposed observing system includes repeat hydrography (*dashed yellow lines*; *solid bold yellow lines* indicate higher frequency repeat lines); basin-scale arrays of moorings and repeat hydrography for main transport lines (*bold black lines*); and moored arrays across deep boundary currents and interbasin exchanges (stars) and in the primary AABW outflows (hexagons). *White stars* indicate locations of existing arrays; *yellow stars* indicate recommended new arrays. For clarity, some components of the proposed observing system are omitted (e.g., floats and broad-scale mooring array, see [129]). Base map from S. Speich, adapted from R. Lumpkin (From [118]; used with permission)

needed in the subpolar and subtropical North Atlantic, at low latitudes, and in the South Atlantic. Based on relevance, feasibility, and the value of continuing existing time series, arrays at 47°N, 26.5°N, 9°N, and 35°S are recommended. The existing monitoring arrays at 26.5°N and 9°N need to be maintained. At 47°N and 35°S, interior measurements of water properties and velocity are needed, as well as boundary arrays and end-point monitoring. Closure of the Labrador Basin with a full-depth transport and flux array is also recommended to monitor the production and export of Labrador Sea Water, an important contributor to the Atlantic OC and a region known to be sensitive to climate variability such as the North Atlantic Oscillation.

Measurements of key components of the OC and deep circulation need to be made in additional locations, where basin-wide monitoring is not possible. Existing long-term measurements of dense overflows and boundary currents in the Atlantic must be continued (see Table 1 of [60] for the location of these measurements). A new array is needed at Cape Farewell to measure the combined flux of the Denmark Strait and Faroe Bank Channel overflows [128]. Monitoring of the boundary currents in the South Atlantic needs to be enhanced [129]. The major pathways for interbasin exchanges (the Southern Ocean and Indonesian Throughflow) need to be monitored [130–132]. The southern hemisphere dense overflows and boundary currents carrying ventilated water northward also need to be measured for a complete understanding of the global OC [133].

Repeat hydrography will remain the backbone of the broad-scale deep ocean observing system [122]. The recommended repeat hydrographic lines are shown in Fig. 12; these lines have been identified as high priority by the Global Ocean Ship-based Hydrographic Investigations Program (GO-SHIP) and

commitments for future occupations exist for most of these sections. On each section, top-to-bottom measurements of temperature, salinity, oxygen, carbon, nutrients, and transient tracers are needed. More frequent sections are recommended near the dense water overflows and boundary currents, where the signal of change is evolving more rapidly (see [122] for the rationale and recommended sampling frequency for specific sections).

The repeat hydrography program , while essential, is still far from adequately sampling the deep ocean, given the infrequent sampling in space and time. The OceanSITES network of long-term time series stations will make an important contribution [134] and needs to be well-integrated with other deep-ocean observing systems, such as observatories established for geophysics or other applications.

In addition to maintaining the existing observing systems for deep ocean velocity, heat, salt, and carbon, there is a critical need to develop new, cost-effective, technologies for observing the deep ocean. Profiling floats capable of deeper profiling would allow broad-scale, sustained sampling of deep ocean properties for the first time. As well as the technological advances necessary to achieve this, design studies are needed urgently to determine the appropriate investment and deployment strategy for deep floats. Deep gliders could also make an important contribution and prototypes are being tested now that are designed to profile to 6,000 m depth. Near-continuous time series are needed to avoid aliasing and to determine the spectrum of deep variability. The OceanSITES network will make a significant contribution to this goal. Development of long-term moorings with the ability to transfer data to the surface (e.g., using expendable data capsules, acoustics, or other means) is needed to allow time series to be measured in remote ocean locations in a cost-effective manner [129]. Development of new sensors and platforms to measure carbon and other biogeochemical parameters is essential to improve the ability to track the evolving ocean inventory of carbon and acidification.

Status and Prospects

The observing system depicted in Fig. 12 is at various stages of readiness and commitment. Most of the hydrography lines have commitments for ongoing repeats, with a repeat time of 5–10 years. Several lines at high latitude are being repeated more frequently (indicated as solid lines in Fig. 12; see [122] for details). The moored arrays identified in Fig. 12 are, from a technology standpoint, ready to go now. More than 20 moored arrays and repeat lines have already been established in the Atlantic basin, as described in more detail in [60]. Many of these have a multiyear commitment. Each of the Southern Ocean sites identified by hexagons in Fig. 12 has been sampled with a moored array of at least 1-year duration in the last decade. The three Weddell Sea sites have been maintained for more than 8 years and are still underway. There are fewer established, long-term moored arrays in the other ocean basins, although pilot experiments are planned or are underway for most of the sites indicated in Fig. 12.

Overall, a large fraction of the recommended observing system for the deep ocean and OC already exists or is being developed – in particular, those components that rely on existing technology. On the other hand, the tools available today leave vast blind spots in the deep observing system: there are no means of making broad-scale, sustained measurements of the properties and circulation of the deep ocean. Three particular elements that are under development would make this possible: Floats capable of profiling throughout the full ocean depth; gliders capable of full-depth, basin-scale missions; and long-endurance moorings with data telemetry capability. For the nonphysical parameters (e.g., carbon, nutrients, biological variables), new sensors suitable for deployment on autonomous vehicles and moorings are urgently needed.

Future Directions

The overturning circulation and deep ocean strongly influence phenomena of direct relevance to sustainability, including climate change and variability, sea level, temperature and precipitation patterns over land, global biogeochemical cycles, and marine productivity. Despite its importance, observations of the deep ocean remain scarce, limiting the ability to understand and predict the overturning and deep circulations, their response to changes in forcing, and the impact of

change. However, substantial progress has been made in recent years, including the first time-series measurements of the strength of the overturning circulation in the Atlantic, the discovery of new current pathways in the deep ocean, evidence for widespread changes in the deep ocean, and a deeper appreciation of the role of the deep ocean and overturning in the climate system. Building on these advances, the community has recently articulated a strategy for sustained observations of the deep ocean and overturning. New tools are needed before a comprehensive observing system for the deep ocean can be established and many of these technologies are under development. An ongoing challenge is the need to complete the transition from a collection of distinct observing elements to an integrated, coherent observing system.

Acknowledgments

Many of the ideas presented here were developed as part of a community-wide effort to develop plans for a sustained deep ocean observing system, as input to the OceanObs09 process.

AGM Absorptive glass mat, a battery separator material.
Ah Ampere-hour: dc current multiplied by time of charge or discharge.
Monopolar cell String of cells connected in series (+ − + − + −).
Bipolar plate Conductive, nonporous substrate with negative active material on one side and positive active material on the opposite side.
e^- Electron.
Float V Voltage applied to sustain battery Ah capacity.
Flooded cell Lead-acid cell saturated with aqueous sulfuric acid electrolyte.
Gel cell Lead-acid cell with a gelling agent added to the electrolyte.
HEV Hybrid electric vehicle.
KVA Kilovolt amperes, unit of electrical energy in an ac circuit.
H_2SO_4 Reactant at both electrodes; electrolyte when aqueous.
MSDS Material safety data sheet (for information on a battery product).
Pb Lead metal, the main negative electro-active material.
PbO_2 Lead dioxide, the main positive electro-active material.
$PbSO_4$ Lead sulfate, the discharge product on both electrodes.
SLI Starting, lighting and ignition automotive battery.
UPS Uninterruptible power system.
VRLA cell Lead-acid cell with one-way pressure-relief valve.

Definition of the Subject

Work on optimizing battery designs to fit the needs of each emerging application has been an ongoing process

since Gaston Planté first demonstrated the lead-acid battery in France in 1859 [1]. This article describes many different commercial lead-acid battery designs and electrical requirements in a wide range of applications. Commercial lead-acid batteries are increasingly used for sustainable energy storage and power system regulation. Their global availability and the low cost of their components, their reliability under many operating conditions and their established recycling industry are among the reasons that the technology is finding additional markets in sustainable energy systems.

Adapting battery designs to further optimize their performance in new applications has been a successful international effort for 150 years and continues to generate improved battery designs and power systems for the future.

Introduction

A wide range of designs and sizes of lead-acid batteries are manufactured for traditional markets. Examples of applications are automotive vehicle starting, lighting and ignition; stand-by power back-up for electrical and nuclear energy and safety systems; and vehicle propulsion. Growing use of lead-acid batteries for storing sustainable energy has led to new designs with improved performance and longevity. New lead-acid battery designs for hybrid electric vehicles are under development. A recent 144 V Ultra battery design with negative plates made of carbon and lead in a parallel configuration exceeded 100,000 miles when substituted for nickel metal hydride battery in a Honda Insight [2].

The electro-active ingredients of lead-acid batteries, based on lead, sulfuric acid, water and oxygen, are available around the globe. Small amounts of other common materials such as carbon, barium, and lignin from wood are also added. Plate separators, battery cases and other inert parts are generally made from glass and common plastics, such as polypropylene and polyethylene. Another environmental advantage is that a well-developed commercial battery recycling system has a proven record of recycling more than 97% of spent lead-acid cells and batteries in the United States and Europe. These advantages are major reasons why the lead-acid battery has remained the most widely used energy storage device for large-power sustainable energy systems.

Commercial designs range in size from single cylindrical 2-V "D" cells for portable equipment to large strings of prismatic battery modules for both stationary and motive power. A 6 V battery is achieved with a series connection of three 2-V cells in a string, in contrast to the four cells that are required for 6-V nickel-metal hydride or nickel-cadmium batteries. Higher lead-acid battery voltages in multiples of two are made by adding more cells to the string. Batteries for cars with gasoline engines or micro-hybrid systems typically have 6 cells connected in series to produce 12 V. DC standby-power systems that back-up telecommunication systems are usually 24 or 48 V modules. Medium hybrid electric vehicles (HEVs) with power-assist systems have a battery voltage in the range of 100–150 V. Some large stationary applications, as well as full hybrid electric vehicles, require a battery voltage over 200. The practice of balancing individual cells to maintain optimum electrical performance and long battery life increases in difficulty with the battery string voltage.

Lead-Acid Battery Markets

The largest and most familiar market for lead-acid batteries is vehicle starting, lighting and ignition (SLI). In addition to passenger cars and trucks, the SLI market includes batteries for motorcycles, off-road vehicles, motorboats, airplanes, racing cars, and other mobile devices. Only a small percentage of the total energy in the battery is used to start a car at moderate temperatures but the electrodes must have very high surface areas to yield the larger currents needed for cold engine starts.

SLI batteries must also provide higher amp hour (Ah) capacity at the lower currents needed to power the lighting, entertainment, safety, and other on-board electronic equipment. In addition to electrical drains from on-board equipment, batteries lose charge by internal chemical self-discharge processes. In cold weather these processes are slow, but when the vehicle is parked in hot environments, higher self-discharge rates can reduce the battery voltage and current needed for engine starting. When stored in hot environments, vehicles and boats that are not used regularly can fail to start because of these self-discharge processes.

Lead-acid batteries are also used for emergency power in uninterruptible power systems (UPS),

telecommunications back-up systems, and safety equipment in critical applications such as hospitals and nuclear power plants. Stationary or "standby" battery designs and recharge profiles vary according to the specific system requirements. Large battery strings are connected in series to deliver up to several hundred volts.

In telecommunication back-up power systems, stationary batteries are typically charged continuously at low constant voltage, called the "float voltage" or at low constant current to maintain their energy levels. The batteries contain enough capacity to provide emergency power during long electrical outages of 8 h or longer or until a generator can be brought up to power the system. When power outages are short and infrequent and the battery electrical grid is restored, the float charging will continue. For longer electrical outages, a higher charging rate may be specified to recharge the battery as quickly as possible.

Large digital data centers that support online computers have been increasing rapidly in recent years. The market is driven by the very high cost penalty incurred when computers go offline due to a power outage in one of these centers. The batteries are designed to replace ac power and are therefore rated in KVA.

Deep-cycle batteries store and deliver energy for motive power applications, such as golf carts, forklift trucks, and airport service vehicles. Use of batteries to power robots for duty cycles in highly automated or hazardous applications is also growing. The number of charge–discharge cycles that they can deliver during their lifetime is a function both of the cell design and the battery cycle profile.

In a temperate climate zone, batteries used for solar energy storage generally do not undergo repetitive, deep-discharge cycling. Instead the energy storage system is designed to cycle at a daily partial-state-of-charge cycle in which the battery charges on sunny days and discharges when used at night or on overcast days. During the summer, the photovoltaic system will provide extra energy that can gradually increase the battery state of charge. But during the winter months the battery state of charge will gradually decrease. In temperate climates the use profile may, therefore, be shallow daily cycles within a single deep yearly cycle.

Energy from remote wind turbines can be stored in lead-acid batteries designed to accept high power peaks. These batteries may also be used to filter power peaks and maintain grid stability when wind energy is added to the electrical grid system.

Hybrid electric vehicles (HEVs) are a new and even more demanding partial state-of-charge applications. The battery powers the SLI functions but is also used to assist other functions in the vehicle propulsion system. A high current charges the on-board battery when the vehicle brakes are applied. When the vehicle accelerates, the battery discharges rapidly to provide the required power. If the car is parked for long time in a hot environment, the battery can also self-discharge. Although the battery-operating modes depend on the vehicle design and usage, many of these HEV batteries operate in a narrow range between about 30 and 70% state-of-charge [2].

Nickel metal hydride and lithium batteries are also under development for HEVs. However, safety, low cost and readily available materials give lead-acid batteries some important advantages for a consumer mass market. In addition, an industry is already in place and well capable of recycling nearly 100% of commercial lead-acid batteries.

In early hybrid electric vehicle testing, high currents needed for acceleration and regenerative braking and minimal recharge times limited the cycle life of VRLA batteries. Several modifications to the battery design have greatly improved the battery's high-rate performance in typical HEV driving cycles. For example, conductive particles have been added to the electro-active lead material in the negative plate to increase its electrical conductance and its electrolytic capacitance.

The new lead/carbon acid battery design, called the Ultra battery, shows promise for use in HEV and other partial-state-of-charge applications. Scientists at CSIRO in Australia invented the Ultra battery, and Furukawa in Japan has developed a manufacturing process that has been licensed in the United States and Europe.

The Ultra battery design [2] substitutes a carbon electrode for a portion of each negative lead electrode. The combination of the carbon negative and the lead-dioxide positive electrode provides a pseudo-capacitor in parallel with a normal lead-acid battery in the same cell. The pseudo-capacitor can operate at high currents for short periods of time to reduce the stress on the

battery. Meanwhile, the battery can store chemical energy and supply electrical energy for a longer period of time at a more moderate rate.

Sources of Information on Lead-Acid Batteries

Battery manufacturers often classify lead-acid battery designs in their product specifications and data sheets according to the market application. Common terms are described below so that the reader can understand the type and appropriate use of each battery product.

Battery producers provide technical specifications and material safety data sheets (MSDS) for their products. The data sheets are often available on their websites. Section I of the MSDS shows the battery type and name, and the name and contact information of the manufacturer, including customer service and emergency telephone numbers. Chemicals in the battery are listed in Section 2 and physical and chemical characteristics are shown in Section 3. Section 4 lists fire and explosion hazards based on physical and chemical data. Section 5 provides important safety requirements during shipping and electrical installation and use to avoid shorting and electrical fires. Health hazards and precautions for safe handling, use and disposal are provided in Sections 6 and 7. Control measures, if needed, are provided in Section 8. Information on proper transportation, shipping and handling in Section 9 is essential to ensure good battery performance. Battery manufacturers also give additional information, including disclaimers, in Section 10.

Several large organizations have been instrumental in developing the battery industry in a responsible and innovative approach to meeting the needs of its customers. The Battery Council International [3] publishes manuals, specifications, test methods, and other literature for lead battery users and sponsors symposia on the battery industry. The International Lead Association (ILA) is a consortium of companies in mining, battery design and manufacturing, and recycling, their suppliers, contractors, and other organizations that have a direct interest in lead and its responsible use. ILA also manages an international consortium of companies that are doing cooperative research to develop and improve battery technologies for new applications, as well as environment, health, sustainable development and product-related research programs.

Battery Designs

Monopolar and Bipolar Electrodes

Commercial batteries are typically monopolar designs. Monopolar cells are made in a stack of a single positive electrode, a porous, nonconductive separator, and a single negative electrode. To increase the cell capacity, the series stacking process continues with separator/positive/separator/negative layers to produce a larger stack of plates that will deliver the required cell capacity. In each cell the negative electrodes are all connected in series by a conductive lead strap and terminal called the "top lead." The same method is used to connect the positive plates to the positive top lead.

The negative and positive terminals collect the current in each cell and conduct it to the external negative or positive post, respectively. The battery is sealed to avoid electrolyte leakage and air ingress, but one-way pressure relief valves are required to release small quantities of gas that may be generated during recharge. Most batteries have a pressure valve in each cell, but some designs use a single pressure relief valve for all cells.

Bipolar designs have been tested over many years, but are still under development. They are especially desirable for applications that require high voltage and power but can store only limited capacity per unit cell. One developing application is for hybrid electric vehicles. They require batteries with high current capability for short times to store regenerative braking energy and for vehicle acceleration. Each electrode in a bipolar cell has a positive side and a negative side with a solid partition between them that conducts electrons but not ions. The partition material must also be noncorrosive to prevent shorting through the partition walls.

Bipolar electrodes are stacked to produce a battery of cells connected at the partitions. If the cells in a bipolar battery are not rigorously sealed around the edges, electrolyte leaks can provide a shunt current path between cells, which reduces the battery performance. Researchers continue to look at new materials and designs for commercial bipolar batteries. Recent work to develop bipolar batteries is discussed further in Future Development at the end of this article (Fig. 1).

Lead Acid Battery Systems and Technology for Sustainable Energy. Figure 1
Schematic of monopolar and bipolar battery designs [4] (Electrochemical Society approval obtained)

Flat and Tubular Electrodes

Lead-battery electrodes can be made as a flat plate with a lead grid as the current collector or as a tubular plate design with a lead rod current collector in the center of tubes. Monopolar electrode current collectors have a conductive lead grid that connects with the terminal. The current collector physically supports the electrode and also collects and carries the current to the electrical system.

Flat grids are often made by pouring molten lead into a mold and cooling it to form a grid with holes for the active materials. Other approaches to making grids are to punch holes in flat lead sheets or to slit the lead sheets and then expand the slits to make the holes for the active material paste.

Tubular positive plates are sometimes used in batteries for deep-discharge applications to reduce shedding of electro-active materials from the plate during cycling. The positive electrode has interconnected porous tubes that are filled with positive lead paste. Lead rods in the centers of tubes are connected in parallel by a conductive lead bar at the top, and the bar is connected to the positive terminal.

Tubular batteries have flat negative plates opposing the positive tubular plates. Recent approaches to preventing positive plate shedding with improved separator designs have limited the use of tubular positive plate batteries. They are primarily in applications that have deep-discharges or severe vibration.

Lead Alloys in Grids and Gas Venting Systems

Because water electrolysis on pure lead is a very slow process, pure lead grids have good corrosion resistance in aqueous sulfuric acid. However, lead is a soft metal that is easily bent out of shape unless it is alloyed with stronger metals. This problem was solved between 1880 and 1890 by adding up to 12% antimony and a lesser amount of arsenic to the lead. These additives increase the mechanical strength of the grid, but unfortunately they also increase water loss and accelerate hydrogen

evolution when the batteries are charged. Batteries with grids containing antimony are designed to vent the oxygen and hydrogen that water electrolysis produces, but periodic water additions are necessary to maintain life. Higher levels of room ventilation are also required to maintain safety.

Lead-alloys containing calcium were introduced in 1935 by Haring and Thomas of Bell Laboratories [5] to reduce water loss and ventilation requirements. These designs are often called low-maintenance batteries, because water additions are not required and now are often prevented by battery manufacturers to minimize electrolyte contamination. Some of the lead alloys in these designs have lower levels of antimony, typically 1–3%. Others use a combination of calcium and tin in the lead. Specially designed vent valves with a flame arrestor are installed to prevent an external spark from igniting hydrogen gas in the battery.

In about 1970, Sonnenschein in Germany [6] began using finely divided fumed silica to gel the sulfuric acid and reduce acid leakage. The technology was applied to portable or power equipment. At about the same time Don McClelland and John Devitt at Gates Rubber Company [7] invented a valve-regulated lead-acid (VRLA) battery with an absorptive glass mat (AGM). This valve reduces acid leakage while retaining the power capability of a liquid electrolyte system. The spirally wound battery design in Fig. 2, based on the Gates Rubber Company patents, is now manufactured by EnerSys Energy Products, Inc.

VRLA batteries have a one-way pressure relief valve that opens when the internal battery pressure increases to a specified valve design level between 1 and 30 psi. The valve closes when the internal battery pressure decreases. Some VRLA batteries have grids made of pure lead or pure lead with a little tin added. The design intent is to facilitate the recombination of the oxygen and hydrogen within the cell by re-forming the water during charge. This process, often called "the oxygen cycle," can reduce the amount of hydrogen vented over the life of the cell but will not entirely eliminate it. Room ventilation must be adequate to handle a worst-case condition, such as a high battery temperature, when the batteries are on charge. Water electrolysis and hydrogen venting accelerate with increasing battery temperatures during charge. Other options for controlling battery life and safety are monitoring and control of the environment, and smart battery charging using algorithms and electronic control methods.

Lead Acid Battery Systems and Technology for Sustainable Energy. Figure 2
Cutaway of valve-regulated lead-acid cell (EnerSys Energy Products, Inc., approval obtained)

Electrode Active Material Preparation

The electrodes in the first lead-acid battery were made by repeatedly charging and discharging lead plates in sulfuric acid mixed with forming agents to facilitate surface corrosion. Because the electrochemical formation process requires a large amount of time and energy to produce high battery capacity, electrochemically formed plates are now typically used mainly for heavy-duty industrial applications where very rugged plate designs are required.

Today, pasted plates are more common. They are made by mixing lead oxide powders with aqueous sulfuric acid and other minor additives to form a lead oxide paste that can be spread onto a lead grid. Since the negative plate surface area tends to shrink during battery cycling, a mixture of fine carbon particles, lignin derived from wood, and barium sulfate is typically added to maintain a high plate surface area. This additive is called an expander mixture. The expander mix is changing as new battery designs and applications emerge.

Lead Acid Battery Systems and Technology for Sustainable Energy. Figure 3
Cut-away of VRLA AGM battery with low profile (EnerSys Inc., approval obtained)

Electrolyte Systems: Flooded, Gel, and Absorptive Glass Mat (AGM)

The sulfuric acid used in lead-acid batteries is a combination of sulfuric acid (or dihydrogen sulfate, (H_2SO_4) and water (H_2O)). Acid concentrations in automotive batteries are about 35% H_2SO_4. The cells are "flooded" with excess electrolyte to prevent the battery from drying out during use.

Two types of electrolyte systems use methods to immobilize the liquid battery acid. The first design, which was developed in Germany, is called a "gel" battery because finely divided silica is added to "gel" or thicken the electrolyte. Gelling prevents the aqueous sulfuric acid from leaking or spilling if the battery is tipped. The other method, developed in the USA in about 1970, is absorbing a more highly concentrated acid in a porous glass mat (AGM). The acid concentration in the AGM battery was increased from about 35% in liquid and gel batteries to about 40% acid in AGM batteries. This reduces the water volume in each cell and makes the battery more sensitive to dry-out in hot environments. However, the AGM design has the advantage of higher discharge power compared to a gel battery design (Fig. 3).

A spirally wound, 2 V AGM battery was the first VRLA design used commercially. The valve was designed to open at 30–50 psi. The cell was made by stacking single strips of a positive plate, AGM separator, and a negative plate together, rolling the stack up like a jelly roll, and inserting it in a cylindrical case. The design was called a gas recombinant battery because it reduced the amount of water lost in the battery during charge by recombining the hydrogen and oxygen that are formed on overcharge.

Lower electrolyte volumes and higher acid concentrations of VRLA AGM batteries also allowed designers to lower the height of rectangular cases. Since typical rectangular battery containers cannot withstand high pressures, their valve-opening pressures may be only a few pounds per square inch (psi). Gel batteries became VRLA batteries when they adopted one-way pressure relief valves. Most of the Gel and AGM batteries are now rectangular. All of these designs are called VRLA batteries.

Gel batteries are finding a new market in storing energy from solar cell arrays. The acid concentration in gel batteries is similar to flooded lead-acid batteries. One-way pressure relief valves help to retain the water

in hot environments. Compared to AGM batteries, gel batteries are less susceptible to drying out, because they contain more acid.

Battery Discharge Reactions

The lead-acid battery electrolyte (sulfuric acid) participates in the electrode reaction at both the positive and the negative plate when the battery discharges. Sulfuric acid dissolves in water (H_2O) and dissociates into ions in two steps. First, sulfuric acid forms hydrogen and bisulfate ions [1]

$$H_2SO_4 \Leftrightarrow H^+ + HSO_4^-.$$

These ions transport the electric charge between the electrodes. If the sulfuric acid in the electrolyte is very dilute, the bisulfate ion may dissociate further to hydrogen and sulfate ($SO_4^=$) ions: [2]

$$HSO_4^= \Leftrightarrow H^+ + SO_4^=.$$

The total reaction is [3]

$$H_2SO_4^= \Leftrightarrow 2H^+ + SO_4^=.$$

The standard negative electrode voltage on open circuit is $E_0 = -0.358$ V when measured versus a standard hydrogen electrode. During discharge, lead (Pb) oxidizes by reacting with the bisulfate ion and loses two electrons to form lead sulfate ($PbSO_4$). The reaction is [4]

$$Pb + HSO_4^- \Leftrightarrow PbSO_4 + H^+ + 2e^-.$$

The electrons from reaction [4] are transferred through the external electric circuit to the positive electrode, where lead dioxide (PbO_2) is reduced by reacting with two electrons (e^-), as well as hydrogen and bisulfate ions, forming lead sulfate and water. The reaction is [5]

$$PbO_2 + 3H^+ + HSO_4^- + 2e^- \Leftrightarrow PbSO_4 + 2H_2O.$$

The standard potential of this reaction [5] is +1.690 V versus a standard hydrogen electrode. (May want to use Parsons' book as reference in addition.)

The overall cell reaction is determined by adding reactions [4] and [5] to get the double sulfate reaction [6]

$$PbO_2 + Pb + 2H_2SO_4 \Leftrightarrow 2PbSO_4 + 2H_2O.$$

Reaction [6] is called the double sulfate reaction because sulfuric acid reacts at both electrodes. A resistive layer of lead sulfate crystals forms on both the positive and negative electrode surfaces. The equilibrium cell voltage is the sum of the two electrode reactions:

$$V^0 = +1.690\ \text{V} - (-0.358\ \text{V}) = 2.048\ \text{V}.$$

The voltage decreases as the sulfuric acid concentration decreases. A simple way of determining the relative state of charge of the battery is measuring the battery voltage on open circuit at room temperature. Temperature corrections can be made at higher or lower battery temperatures. Assuming that the battery is at room temperature is usually sufficient unless the batteries have been stored for hours in an uncontrolled hot or cold environment or are operated at high currents.

The theoretical specific energy of the lead-acid battery is calculated below using the molecular weights of the reactants and the chemical formulas. The number of electrons exchanged is an important factor in the energy density of a battery reaction, because it determines the total current that the reactants can deliver. A disadvantage of lead-acid batteries is the high molecular weight of lead. However, the water-based electrolyte is relatively light, and the reaction has the advantage of exchanging two electrons instead of only one.

The number of atoms in these reactions multiplied by the atomic weight of the atom determines the total molecular weight of the reactants:

O weighs 16.0 g/mole($\times$10 moles weighs 160.0 g);
H weighs 1.0 g/mole($\times$4 moles weighs 4.0 g);
Pb weighs 207.2 g/mole($\times$2 moles weighs 414.4 g); and
S weighs 32.1 g/mole($\times$2 moles weighs 64.2 g).

The total equivalent molecular weight of the reactants required to generate 2 moles of electrons in the discharge reaction is 646.6 g.

The calculation of the theoretical specific energy is shown below. The theoretical specific energy at 2.048 V is 170 W h/kg of material weight.

$$170\ \text{Wh/kg of reactants} = \frac{2.048\ \text{V} \times 2\ \text{moles e}^- \times 96{,}500\ \text{As/mole e}^-}{646.6\ \text{g reactants} \times 3600\ \text{s/h} \times 1\ \text{kg/1000 g}}$$

This type of calculation can be useful as a means of comparing the theoretical specific energies of different

batteries. Practical energy densities are design dependent and typically deliver no more than 20–40% of the theoretical specific energy.

Battery Discharge Rates

The reversible voltage of 2.048 V is for the lead-acid battery at a room temperature of 25°C and one atmosphere pressure in a dilute acid concentration. Lead-acid batteries have higher acid concentrations when fully charged, so the reversible voltage is higher. During discharge the reversible voltage drops rapidly at the beginning of the discharge until it reaches an initial voltage plateau. Then the voltage decreases more slowly to the discharge cut-off voltage. The initial drop is in part due to the internal resistance of the battery and in part due to the initial rapid depletion of the sulfuric acid concentration at the surface of both the positive and negative electrodes.

The actual discharge capacity is the current (I) multiplied by the discharge time (t) in ampere hours. The rate of discharge, or current, strongly affects the initial voltage drop and the slope of the plateau voltage. The higher the discharge rate, the shorter the discharge time and the smaller the capacity will be. This is because hydrogen and bisulfate ions must carry the charge between the electrodes through the porous separator and acid film at the electrode surfaces.

The horizontal x axis is the log to the base 3 of the discharge current, and the vertical y axis is the log to the base e in discharge time.

The discharge time is a function of discharge current. $I^n t = C$ where I is current in amperes and t is the discharge time in hours for a specific battery design measured at three or more discharge currents and C is a constant. When these values are plotted on a log–log scale, the constant n is the slope of a straight line. It is typically 1.3–1.4 but approaches 1 at very small currents and 2 at high currents. The example in Table 1 and Fig. 4 is based on three discharges of a VRLA battery.

The discharge reactions are reversed when the cell is recharged. If each of these discharge reactions is reversed and the discharge reactions are added together, the reaction [7]

$$2PbSO_4 + 2H_2O \Leftrightarrow PbO_2 + Pb + 2H_2SO_4$$

is the reverse of the double sulfate reaction [6].

Lead Acid Battery Systems and Technology for Sustainable Energy. Table 1

Discharge amperes (I)	Discharge hours (t)	Ampere hour capacity (AH)[a]
5	9	45
12	3.6	43.2
25	1.4	35
$\ln C = n \ln I + \ln t$		
$4.078 = 1.15 \ln I + \ln t$		

[a]Based on three discharges of one battery

Lead Acid Battery Systems and Technology for Sustainable Energy. Figure 4
Relationship between the discharge time and current in a lead-acid battery

When the battery reaches a voltage level that corresponds to about 90% state of charge, the recharge reaction becomes less efficient as water in the electrolyte begins to form oxygen at the positive plate and hydrogen at the negative plate. This process accelerates as recharge currents and/or internal cell temperatures increase. To control water electrolysis, the charging current is generally decreased as the battery receives its finishing charge. Many lead-acid battery designs are able to recharge up to the gassing level relatively quickly, but the finishing charge will take longer to avoid rapid water loss and high gassing rates. The battery manufacturer's recommendations should be carefully followed, since charge methods and charging times are design-dependent.

Overcharge Reactions

Overcharge is defined as the amp hours of charge put into the battery in excess of the amount of Ah taken out of the battery during the previous

discharge. Because charging is not 100% efficient, all lead-acid batteries must be overcharged to return them to full capacity.

The finishing charge and overcharge reactions that electrolyze water form a mixture of hydrogen (H_2) and oxygen (O_2) gases. At the positive plate, [8]

$$H_2O \Rightarrow 2H^+ + {}^1/_2\, O_2 + 2e^-$$

at the negative plate [9]

$$2H^+ + 2e^- \Rightarrow H_2.$$

The total overcharge reaction is the electrolysis of water to form oxygen and hydrogen [10]

$$H_2O \Rightarrow H_2 + {}^1/_2\, O_2.$$

Thermodynamic measurements of these reactions at platinum electrodes show that it takes less energy to electrolyze water in the electrolyte than to recharge lead sulfate. If this were true in the lead-acid battery, it could not be recharged. Lead-acid batteries recharge efficiently because of the low rate of water electrolysis on lead. The reason is that the hydrogen evolution reaction is impeded on the surface of the lead electrode. As a result, the lead-acid battery can deliver a higher voltage than other aqueous rechargeable batteries.

Impurities in the battery electrolyte lower the cell voltage and may increase water loss. When electrolyte purity is well controlled, the capacity can be returned more rapidly because the end of the recharge is more efficient. The final part of the recharge is controlled either by "floating" the battery at a voltage that is slightly above the open circuit or by applying a small "trickle" current to the battery. Floating or applying a trickle current near the end of charge minimizes the water loss.

The oxygen generated at the positive electrode is not very soluble in the sulfuric acid, so it vents out through the battery valve. However, in a VRLA battery, the oxygen cycle recombines the oxygen and prevents hydrogen from forming at the negative electrode by the following equations.

The positive plate reaction is [8] $H_2O \Rightarrow 2H^+ + {}^1/_2\, O_2 + 2e^-$ shown previously. The negative plate reactions may be a two-step process: [11] $Pb + {}^1/_2\, O_2 + H_2SO_4 \Rightarrow PbSO_4 + H_2O$ and [12] $PbSO_4 + 2H^+ + 2e^- \Leftrightarrow Pb + H_2SO_4$. When these equations are added up, the overall reaction is the double sulfate reaction [1] discussed above

$$2PbSO_4 + 2H_2O \Leftrightarrow PbO_2 + Pb + 2H_2SO_4$$

Since the oxygen generated at the positive electrode is not very soluble in the acid, it will vent out through the valve of a flooded lead-acid battery, and the opportunity to reform the water will be lost. A VRLA battery design allows the oxygen to travel to the negative plate through the AGM separator, because the separator pores are not fully saturated with acid. The acid volume is reduced in the separator by decreasing the percentage of water in the electrolyte. Because of the higher acid concentration, there is free space for oxygen to travel from positive to negative electrode as a gas instead of dissolving in the electrolyte. The oxygen reacts at the negative plate to reform water, because the negative electrode surface has a three-phase gas/liquid/solid interface.

Battery Maintenance and the Effect of Temperature

Lead-acid batteries have a variety of failure modes that depend on the design, the use mode, and the environment. Manufacturers generally provide information about the life of their battery designs in a particular application. Some factors that can shorten the useful battery life are, however, applicable to most designs and applications. One of the most important variables in predicting battery life is the ambient temperature.

Low ambient temperatures reduce the battery voltage and current while high temperatures reduce battery life. For example, automotive batteries often fail to start the engine in the winter for two reasons. First, the power (voltage times current) that is required to start a cold engine increases. And second the battery power is reduced because cold temperatures decrease both the voltage and current that the battery can deliver. High summer temperatures decrease battery life because of increased grid corrosion and other side reactions that lead to battery failure.

Although automotive batteries often fail to start a vehicle in the winter when the ambient temperature is low, battery storage at high temperatures is often the cause of the battery deterioration and failure. If the battery is subjected to high heat for a long time,

reactions that wear out the battery, such as grid corrosion, water loss, and formation of hard lead sulfate on the plate surfaces, will be accelerated.

Application of batteries in other uncontrolled environments, such as outdoor telecommunications cabinets, photovoltaic systems, and marine uses also reduces battery life. When batteries are operated in hot environments, manufacturers often recommend reducing the charging current or float voltage to prevent the battery from overheating.

Battery life can also be reduced by storage on open circuit for a long time. Chemical reactions will self-discharge the battery gradually over its "shelf life." Since heat increases the rates of these chemical reactions, the battery shelf life will be longer if the battery is stored at a moderately cold temperature. The rates of most battery degradation mechanisms are reduced at low temperatures. The electrolyte in a fully charged battery does not freeze until the temperature reaches about minus 40°C. However, the battery freezing temperature will rise to 10–15°C when the battery is discharged.

Future Directions

Increasing use of renewable energy from wind turbines will increase the need for batteries with both higher power and increased energy storage. Wind is variable and tends to be higher at night when electricity is used less by energy consumers. When wind energy is fed into the ac electric grid, this variability frequently causes instability in the grid system. Several new approaches to developing higher-power lead-acid batteries for renewable energy storage are discussed below.

The thixotropic gel that is typically used in VRLA batteries is liquefied by agitation before being poured into the cell. It then solidifies around and within the plate separators. C&D Technologies developed a battery using a colloidal, poly-silica gel that does not have to be liquefied before it is poured into the cell. The gelling solution can be added after the AGM separator between the plates is soaked with acid, so less gel penetrates into plate area. The AGM separator maintains the high power capability of the AGM battery design, while the gel around the edges of the plates provides an additional source of aqueous electrolyte. This extends the cycle life by reducing the rate of water loss. This concept has been tested in a commercial 485 Ah C&D model 12SL 78-13 battery, which is designed for motive power and materials handling equipment [8].

Lead-acid batteries with high power capability may be required to stabilize the future grid system as more wind energy is fed into it. Use of a battery/capacitor combination may be necessary, but the physical space of the system must also be acceptable. The Ultra battery [2], which has both a super capacitor and a storage battery in the same module, is one very interesting way to address this need. In 2010, a 144 V Ultra battery design passed a 100,000-mile test in a Honda Insight at the Millbrook test track in the United Kingdom with no conditioning and in an excellent state of health. After passing that test, the battery was returned to Furukawa in Japan for continued use (Fig. 5) [2, 9].

If the history of lead-acid batteries is an indicator, the performance of a super capacitor and storage battery combination will likely be improved further as additional materials and designs are developed and field experience with the HEV and wind energy applications increases. Other sustainable energy systems that operate over a wide range of currents may also benefit from this work. Many types of carbons as well as other materials are being studied. The challenge is to find materials that are low cost and are also compatible with the lead-acid system.

High battery voltages and power capacities in a small footprint will also be needed to power equipment in off-grid applications. Bipolar lead-acid batteries are most desirable for high voltage applications that do not require large amounts of energy. Researchers continue to look at new materials and designs that will improve the life and performance of bipolar batteries. Atraverda Ltd. in the U.K. uses Ebonex®, a ceramic material based on conductive titanium oxides, for its bipolar battery partitions and case.

Effpower® tested a lead infiltrated ceramic (LIC™) bipolar battery in a Honda Insight for 15,000 km in Gothenburg, Sweden [9]. Their conductive ceramic has pockets containing lead on the negative side and lead dioxide on the positive side of the partition. They have announced plans to start production of 24 V and 150 V lead-acid battery modules in 2011 in partnership with Banner Batterien in Austria. Both batteries are 6 Ah designs. The 24 V lead-acid battery module is rated at 5 KW/8.6 kg in a 90 × 253 × 203 mm

Lead Acid Battery Systems and Technology for Sustainable Energy. Figure 5
Diagram of the construction of the Ultra Battery (Furukawa permission obtained)

module (0.58 KW/kg). The 150 V lead-acid battery module has 0.8 KW/kg. An Effpower® battery has also been installed in a 2007 Honda Civic Hybrid and is undergoing testing at the Millbrook testing grounds in the UK [9].

Bipolar batteries are susceptible to two failure modes that are not found in monopolar designs. (1) When seals around the outside edges of bipolar partitions fail, leakage currents between cells will cause a decline in cell performance. (2) An electrical short through a pinhole in the bipolar partition can cause sudden battery failure. Much progress has been made in bipolar module technologies. Finding the right materials, designs and construction technologies, and improving our understanding of application modes, will be ongoing as new bipolar battery designs are developed and applied.

Glossary

Aquaculture The farming of aquatic organisms, including fish, mollusks, crustaceans, and aquatic plants. Farming implies some form of intervention in the rearing process to enhance production, such as regular stocking, feeding, and protection from predators. Farming also implies individual or corporate ownership of the stock being cultivated.

Co-product allocation Partitioning the input or output flows of a process or a product system between the product system under study and one or more other product systems.

Functional unit The quantified function provided by the product system(s) under study, for use as a reference basis in an LCA, e.g., 1,000 h of light.

Life cycle assessment (LCA) An ISO-standardized analytical tool developed to evaluate environmental performance of products and processes. It constitutes a compilation and evaluation of the inputs, outputs, and potential environmental impacts of a product system throughout its life cycle; the term may refer to either a procedural method or a specific study.

System boundary Defines the inputs and outputs that are included in the study. System boundaries should be set depending on what will be relevant to the aim of the study.

Definition of the Subject

Aquaculture production has grown three times faster than the livestock sector since the 1970s, becoming a major source of edible seafood and other products. This rapid expansion has, however, had a combination of positive and negative environmental, social, and economic effects. A variety of tools are available to evaluate these impacts in an attempt to identify the most sustainable practices. One of the more recent tools that has been applied to the evaluation of aquaculture production is Life Cycle Assessment (LCA), an ISO-standardized biophysical accounting framework that allows for multi-criteria environmental performance assessments. This chapter reviews studies that have applied LCA to studying the environmental dimensions of aquaculture production to date. Methodological differences and alternative approaches are discussed, along with their influence on research outcomes. There is little homogeneity between the studies when it comes to the choice of functional unit, system boundaries, and basis for allocation. However, several clear trends do emerge that point toward imperatives for sustainable practices in aquaculture and considerations for sustainable development of the industry moving forward. Recommendations for further methodological development of LCA for application to seafood sustainability research are advanced.

Introduction

Society is increasingly aware of both the drivers and consequences of natural resource depletion and environmental degradation. Various analytical frameworks have therefore been developed for the purpose of evaluating the environmental performance of products and processes. Finding a suitable tool for assessing sustainability in the rapidly developing aquaculture sector has gained increasing profile over the past 2 decades. What has emerged is the need for a tool that can incorporate multiple environmental performance criteria in the evaluation of diverse aquaculture production technologies. For this reason, there is increasing interest in, and application of, life cycle assessment (LCA) as a research framework to better understand environmental performance in this sector. The interest has, however, not been coming from within the aquaculture industry itself, but rather outside. LCA is a versatile methodology that is well suited to address a broad suite of resource use and emissions-related issues. Over the last decade, it has become an increasingly common tool for characterizing an important subset of environmental impacts in aquaculture and elsewhere.

Aquaculture Development

Even though global capture fisheries landings have declined since the late 1980s, total production of marine fisheries products has increased 67% between 1970 and 2007 (including brackish water fish). This has only been possible through a large increase in aquaculture production over the last 4 decades. Aquaculture currently provides half of all finfish destined for human consumption. Seafood from all sources accounts for about 20% of all animal proteins consumed by humans, and demand continues to grow [1]. The aquaculture industry is the fastest growing animal products' sector, with an average annual growth rate of 6.9%. At present, it provides almost 8 kg of seafood per capita year^{-1} globally [1]. In 2006, aquaculture accounted for more than 70% of global shrimp and prawn production, 47% of total food fish production, and 36% of total fish production. Mariculture of finfish dominates production in developed countries [2]. By mass, however, the majority of global production is accounted for by carp farmed in extensive and semi-intensive farms in Asia.

Aquaculture comprises an enormous diversity of farming technologies, culture settings, and species. From monoculture to polyculture systems operated in ponds, raceways, land-based tanks, along with cages, pens, poles, rafts, and longlines in open water settings, well over 250 species are currently in culture. Production technologies may also reflect traditional farming methodologies or more modern systems [3–5]. In turn, post-production processing yields a diverse range of products, including salted, dried, smoked, and various kinds of preserved fish. About 37% of all fish and fishery products are traded internationally, with the major importers being Japan, the USA, and Spain [1].

Aquaculture and the Environment

It has been proposed that aquaculture represents the most viable option for meeting future demands for fish, as well as providing economic and nutritional benefits to millions [1]. The recent rapid expansion of this sector has, however, been accompanied by a range of environmental and social concerns, including localized nutrient enrichment or depletion, chemical pollution, genetic pollution, introduction of non-indigenous species, habitat destruction, greenhouse gas (GHG) emissions, depletion of wild fish stocks, inefficient energy and biotic resource usage, and spread/amplification of diseases and parasites [2, 3, 6–9]. Of these, local-scale interactions have traditionally attracted the most attention. However, global scale interactions such as greenhouse gas emissions associated with intensive production strategies are of increasing interest. What has become clear is that each production strategy is characterized by a unique suite of environmental interactions at local, regional, and global scales. Informed decision making for improved environmental management in aquaculture, therefore, requires tools, which can provide multi-criteria environmental performance assessments and make clear the environmental trade-offs associated with specific aquaculture technologies and products.

Sustainability Tools in Aquaculture

Increasing aquaculture production to meet future demands is clearly attractive from a policy and development perspective. However, a number of critical questions related to growth in this sector must be

addressed. These questions encompass complex issues associated with sustainability objectives at local, regional, and international scales. For example, a spectrum of negative ecological and social externalities associated with aquaculture and other food production systems bear careful scrutiny and must be weighed against anticipated benefits [10]. Such comparisons need to extend beyond short-term gains and localized impacts and incorporate a long-term social-ecological resilience perspective. This requires tools to identify the most sustainable aquaculture practices, drawing knowledge from both new and traditional culture systems [5].

A wide range of tools/frameworks for assessing various aspects of environmental performance have been advanced [11], some focusing especially on food production. These include techniques such as Risk Assessment, Ecological Footprint, and Energy Analysis. Frameworks more specific to assessing seafood production systems are Fishprint and the Global Aquaculture Performance Index (GAPI) [10, 12, 13]. Most of these, however, encompass a limited range of the environmental concerns associated with aquaculture and some suffer from a lack of methodological standardization [10]. Moreover, the degree of scientific rigor in both the methods and their application is also variable. Data limitations and analytical scope have, therefore, often led to misrepresentation of the environmental consequences of specific management decisions.

LCA – The Method and Its Applicability in Aquaculture

History of LCA

LCA has, since its emergence in the 1970s, evolved from a tool whose primary application was waste management and energy efficiency management to a more general eco-efficiency measurement framework. It has close links to energy analysis, but is unique among biophysical accountancy-type tools in that it has been internationally standardized (ISO 14040-14044) [14, 15]. An LCA typically begins at the "cradle" of a product or service life cycle (i.e., at the point of primary resource extraction), and extends along the supply chain to encompass all life cycle stages of interest to a particular analysis. Single or multiple impact assessment methods may be applied. Estimation of the cumulative environmental impacts along supply chains permits attention to spatially and temporally discrete impacts not typically considered in more traditional environmental impact analyses. Impact categories range from highly quantifiable effects, such as greenhouse gas emissions or energy use, to (less frequently) more diverse social consequences, such as human health effects [16].

The outcome of a LCA is highly influenced by the ambition, skill, and objectives of the practitioner. Modern software with built-in inventory databases and impact assessment methods has simplified the LCA process, to the extent that an aquaculture system may be modeled in hours. However, the rigor of such models is to a large extent dependent on data quality. While use of generic data available in many public and commercial life cycle inventory databases may provide a starting point for scoping analyses, more context-specific data is required for robust modeling of specific production systems and technologies. Unfortunately, the former (simplified analyses) are increasingly common in the peer-reviewed literature, providing what may be misleading signals and eroding the credibility of the research framework, generally.

Software Tools and ISO

The rapid evolution and adoption of LCA have been accompanied by the creation of a variety of guidelines, manuals, and dedicated software [17]. The most commonly used LCA software platforms are GaBi and SimaPro, which are commercial products. Others, such as CMLCA and openLCA, are available free of charge. There are also several life cycle inventory databases, which have been developed, with the most extensive being the EcoInvent database (www.ecoinvent.ch). Such databases provide inventory data for materials and processes common to most product systems – for example, the production of materials such as concrete, steel, and plastic; the provision of energy carriers such as diesel or regionally specific electricity mixes; or transportation modes like air freight, rail freight, or private automobile transport. As these "background" data are often premised on different methods, assumptions, and rigor, sourcing data should be done with care as different databases apply different methodologies. It is therefore recommended to be consistent when

choosing sources of background systems data and also to be aware of the methodology used before making comparisons between studies. ISO compliance does not require that studies are comparable, only that they follow the same requirements. Individual studies also often differ in functional unit (the unit of output against which impacts are quantified), system boundaries, and allocation criteria.

A LCA study is, in accordance to ISO standards, carried out methodically through four phases (Fig. 1). As an initial phase, the goal and scope definition will specify the main characteristics of the study. Goal is specified as the application, audience, and reason for the study, while scope outlines the product system to be studied, functional unit, system boundaries, allocation procedures, impact categories, data requirements, assumptions, limitations, data quality, and format of the report. System boundaries specify the processes that are to be included in the product system and are in turn set by the cutoff criteria. This is followed by a Life Cycle Inventory Analysis (LCI), which involves the collection and calculation of data as well as allocation of burdens, in cases where input or output flows involve more products or processes than the defined unit. The impacts of these results are then, in the third phase (Life cycle impact assessment, LCIA), assessed according to their contribution to the impact categories defined in the goal and scope phase. Finally, the three previous phases are interpreted and communicated to the anticipated audience.

Functional Unit

Seafood commodities are farmed for different purposes, which complicates the choice of functional unit. Most LCA studies to date have used live weight mass at the farmgate or mass of processed product as the functional unit. Variable protein contents and edible portions between aquatic animals therefore may complicate direct comparisons. For example, the edible portion of an oyster is only about 18% of its wet weight, a number that in turn is subject to local variation [18] while the edible yield from an Atlantic salmon (*Salmo salar*) typically exceeds 50%. Local customs may

Life Cycle Assessments and Their Applications to Aquaculture Production Systems. Figure 1
The general methodological framework for LCA studies according to ISO 14040 (2006) and its four comprised phases

further confound the decision as certain parts of the fish that may be discarded as inedible in one region are considered good for human consumption in another region. Two such examples are herring roe and catfish stomachs; both of which are considered offal in the western world but are prized in parts of Asia [19, 20]. Ideally, the functional unit should reflect the function of the product system. For aquaculture products intended for consumption as food, such functions might include the provision of caloric energy, protein, or omega fatty acids, etc.

Setting System Boundaries

System boundaries delineate those processes formally included in an analysis from those that are excluded. There are only general requirements on how to set these boundaries, though they should be decided relative to the research objectives and include all elements having a non-trivial influence on research results. Most LCA studies in aquaculture limit their system boundary to the farmgate, whereas some include processing, packaging, marketing, and consumption phases [21–23]. Thrane [24] evaluated the effects of post-harvest stages of the life cycle of seafood products and concluded that they have a significant impact on the overall environmental performance of most seafood products. For example, inclusion of the processing phase contributed an additional 10% to life cycle energy use, while inclusion of the consumption phase resulted in an average 25% increase in cumulative energy demand [24].

Allocation

A common issue faced by many LCA practitioners is how to allocate environmental burdens to products and materials that are co-produced with other products [25]. Examples in aquaculture include the allocation of environmental burdens between targeted catch and bycatch used in fishmeal production, the multiple products derived from corn and other commodity crops used in feeds, and alternative uses of fish by-products or aquaculture wastewater used to fertilize other crops. The ISO standards for LCA do provide guidelines for an allocation decision hierarchy, but leave considerable room for interpretation. According to the standard, environmental burdens are primarily to be allocated according to an underlying physical relationship, if subdivision is unavoidable. The standard further states that where such relationships cannot be established, the allocation should reflect other relationships between the input system and output system. In reality, the final choice of allocation basis will likely reflect the goals of the study, as well as the worldview of the practitioner. Some of the more common bases for allocation in aquaculture and their characteristics are summarized in Table 1. Accessibility of the different allocation factors differs depending on location and situation, where regional differences will play a large role in making generalizations. Time and spatial scales will also have a great influence on the allocation factors that do not represent physical relationships, as these will not remain static.

There are several things to keep in mind when choosing a basis for allocation. The first is that nothing limits a study to only one allocation factor; each allocation scenario may be treated differently depending on the circumstances. Results may also be presented using several of the allocation factors, thus enabling readers to interpret results according to their own perspective or worldview. No matter how the allocation problem is approached, it is very important to be clear in the supporting text about which methods have

Life Cycle Assessments and Their Applications to Aquaculture Production Systems. Table 1 The most commonly used bases for allocation and their characteristics

Allocation factor	Accessibility	Physical relationship	Static	Market oriented
Mass	Good	Yes	Yes	No
Value	Average	No	No	Yes
Nutritional energy content	Average	Yes	Yes	No
System expansion	Poor	Sometimes	Sometimes	Sometimes

been used. It is, however, important to keep in mind that the basis of allocation can influence the allocated burden by as an order of magnitude [26].

Impact Categories and Impact Assessment

Any quantifiable performance measure can be included within the LCA methodology, from emissions to the well-being of workers, as long as: (a) a causal relationship between the variable of interest and the provision of the functional unit can be established and (b) a defensible impact assessment methodology is available [27]. A wide variety of impact assessment methods are available for use in LCA, most of which have been applied to assessments of seafood production systems [27]. These methods may describe environmental interactions that have relevance at local (e.g., eutrophication), regional (e.g., acidification), or global (e.g., greenhouse gas emissions) scales. Generally, impact assessment methods are based on peer-reviewed, internationally accepted environmental accounting protocols. Some of these continue to evolve, and novel methods emerge in response to newly identified issues [27, 28].

Labor

Labor is rarely accounted for in LCA due to the difficulty of establishing defensible system boundaries and quantifying associated environmental impacts. It can also be debatable if the number of employees should be considered as a negative or positive input. It is, however, important to keep labor in mind when comparing traditional and modern production systems. Labor can be presented in a number of different ways, either separately or incorporated into the individual impact categories [28, 29]. Several methods have been suggested on how to quantify the environmental impacts of labor. Suggested reference units include metabolic energy, calorific content of food consumed, national fuel share, or other more complex equations [29].

LCA in Food Production

Working with non-Static Systems

The adaptation of LCA from the characterization of static industrial systems to food production systems typified by significant variability has brought with it new challenges. Annual fluctuations occur both on the farm, as productivity will depend on water temperature, extreme weather events, algae blooms, etc., as well as on indirect variables such as oil prices and public demand. Fisheries providing fishmeal and fish oil for use in aquafeeds offer a good example of such variability, as fuel inputs per tonne of fish landed will fluctuate with season, stock status, gear type, and skipper [30, 31]. The aquaculture sector is particularly dependant on annual production of the anchoveta fishery off South America for both of these commodities, which in turn is strongly influenced by El Niño-Southern Oscillation (ENSO) events [32]. Increased use of compound feeds and higher oil prices have also boosted prices of both fishmeal and oil over the last decade [1]. Such fluctuations not only affect economic allocation but also catch per unit effort. It can therefore be hard to set average fuel consumption for fishing fleets, especially since the species and status of the stocks used for fishmeal production often are unknown [33]. The situation is further complicated in certain parts of the world where low value fish are used directly as fish feed [33].

Agricultural crops – the other major source of aquafeed inputs – may also experience significant annual fluctuations, with larger variability in developed countries, for crops such as maize and wheat [1, 34]. Farmgate prices will further affect the LCA as many feed formulators and aquaculturists quickly adjust to price trends in their choice of feed inputs or cultured species in efforts to maximize profits [20, 35]. One such example is the constant push toward higher stocking densities of shrimp in SE Asian polyculture systems, where the large profits that are to be made often outweigh the risk of white-spot disease [36]. Farming practices, as for feed composition, are also under constant change, which emphasizes the importance of considering the time scales used in LCA studies. Ultimately, a balance must be struck between feasibility and the goals of the study in pursuing representative data and models.

The relevance of such variability will, in part, be determined by the scope of the analysis and specific research questions of interest. Variability might be accommodated when modeling at regional scales by applying average data over specified spatial and temporal horizons. It is increasingly common to account for and report such variability in published outcomes. In other cases, quantifying variability might comprise

research foci – for example, understanding the influence of variable field-level nitrous oxide emissions on the overall greenhouse gas intensity of crop production at local scales.

LCA in Aquaculture

The first LCA studies focusing on aquaculture systems were conducted in the beginning of the new millennium, with an increasing application of the methodology to aquaculture issues toward the end of its first decade [37–39]. As the number of studies increased, so too did the seeming detail of analysis and possibly also the accuracy of the results. Most have focused on production systems in developed countries (see Table 2). The methodological detail used between studies does, however, vary widely and makes broad comparisons between studies difficult. This includes differences in functional unit, system boundaries, data sources and quality, and choice of allocation criteria.

A common theme that has emerged from LCA research of intensive, finfish aquaculture production systems is the importance of feed provision in supply chain environmental impacts [21, 22, 42–44]. For example, Pelletier et al. (2009) found that feed provision accounted for, on average, 92% of quantified impacts in global salmon farming systems. Of particular importance are fisheries and livestock products, which typically have higher impacts per unit mass relative to crop-derived feed inputs (Fig. 2). Also of note is that on-site processes have only made a substantial contribution in highly mechanized systems, where industrial energy inputs are required to maintain water quality [3, 20, 21, 40, 44].

Although animal-derived feed ingredients usually have a higher impact per unit mass compared to crop-derived inputs [22, 43, 45, 46], their inclusion may support more rapid growth of the cultured organisms and, in some cases, result in a higher quality product [47]. By including a larger portion of agriculturally sourced materials in feeds, environmental burdens may be reduced. In this light, it might be anticipated that rearing herbivorous or omnivorous species is environmentally preferable. However, both feed composition and feed conversion efficiency must be considered in determining and comparing impacts between cultured organisms [44].

The choice of impact categories in aquaculture LCAs varies widely (Table 2). These include resource depletion and emissions-related environmental concerns, as well as toxicological potentials. The only categories almost consistently applied are global warming potential, acidification, and eutrophication, while cumulative energy demand is also very commonly evaluated. There is an expected but imperfect correlation of cumulative energy demand and global warming potential (Table 3), since much of the feed-related emissions for agricultural inputs do not arise from fossil fuel combustion. Rather emissions of nitrous oxide and methane are typically as or more important. It is only in systems where ecosystem services have been replaced to a large extent by anthropogenic processes that on-farm energy demand has a significant impact on the total energy consumption.

Guiding the Way for More Sustainable Aquaculture and Alternative Farming Methods

Feed Production

Improvements of feed conversion ratios (FCRs) for piscivorous fish in addition to an increased inclusion of non-fish ingredients has led to great environmental improvements over the last decades [46]. Additional improvements are to be made by identifying and sourcing for the least-environmental-cost feed formulations; especially for sources of fishmeal and oil [22]. In reduction fisheries, effective management will play a major role in reducing fuel consumption along with associated environmental impacts while sustaining output from the industry [30, 50]. In many fisheries, boats today have to travel further to find productive fishing grounds and invest more fishing effort to maintain catches. This has resulted in a sixfold increase in energy consumption for some capture fisheries over the last two decades [51]. A collapse of one of the large reduction fisheries, of the scale that occurred to the anchoveta fishery in the 1970s, would further drive up the energy intensity of aquafeeds and culture products as well as have devastating effects on the aquaculture industry as supply of fishmeal and oil supplies already are outpaced by demand [1, 52].

Decreasing fishmeal inclusion has, to a large extent, been driven by increasing public awareness about "fish-in to fish-out" ratios, as a result of labeling and

Life Cycle Assessments and Their Applications to Aquaculture Production Systems. Figure 2
Cumulative Energy Use and Greenhouse gas emissions from salmon production. Feed production is by far the largest contributor to environmental concerns, constituting 93% of the energy use and 94% of the GHG emissions. The feed represents an average from farms in Norway, UK, Canada, and Chile with 41.8% of the ingredients derived from crops, 49.4% from fish, and 8.8% from livestock. Data from: Pelletier et al. [22]

certification initiatives [9, 46]. It has also been strongly influenced by rising prices for these commodities, due to increased competition from the aquaculture sector [1]. The overall demand for fishmeal and oil in aquaculture has, despite this, increased due to a larger share of farmers using compound feeds and increasing aquaculture production over time [46, 53]. At present, in most aquaculture LCAs, the amount of fishmeal and oil used is only reported as life cycle inventory data. Beyond the standard impact categories, methods to account for the ecological impacts of producing these products are underdeveloped. To date, only a few researchers have, e.g., applied a measure of biotic resource use in life cycle assessment, following the methods originally advanced by Pauly and Christensen [54]. This method quantifies the net primary productivity, as measured in carbon, required to support the provision of a specified amount of fish-derived material, taking into account trophic level and species-specific meal and oil yield rates. Biotic resources used can differ by as much as an order of magnitude between different sources of fishmeal and oil [22]. Alternative sources of proteins that could in part replace fishmeal include soy meal, wheat gluten, bone, feathers, blood, livestock co-product meal, and seafood processing materials [46, 55]. A variety of vegetables oils may also be partially substitutable for fish oils. The environmental performance of systems using, e.g., agriculture alternatives for fishmeal and oil needs, however, to be carefully analyzed as such substitution does not guarantee improved performance. Switching to the culture of low-trophic species is often described as a solution for more sustainable aquaculture [6]. While this would allow for great reductions in fish inclusion rates, the higher FCRs associated with lower quality feeds may result in only marginal improvements in GHG and related life cycle impacts [44]. In contrast, a switch to more energy and climate-friendly fertilizer production either through efficiency improvements in existing fertilizer plants or the use of biological nitrogen fixation in place of conventional N fertilizers could, however, offset some of the impacts associated with crop production [56, 57].

Improvements of feeding practices on farms can both reduce costs, emissions, and FCR [58]. The amount of feed added is often calculated according to feeding charts or as a percentage of the fish biomass. These generalizations often result in inefficient feed

Life Cycle Assessments and Their Applications to Aquaculture Production Systems. Table 3 Summary of the different results for 1 t of seafood product at farmgate

Species	Country	Source	CED (MJ) t^{-1}	GWP kg CO_2-e t^{-1}

Energy use in Norwegian salmon farming reported by Ellingsen and Aanondsen [39] was calculated by assuming that 15% of total reported energy use was used in the processing and distribution phases

utilization as it does not take factors such as species, genetic stock, feed composition, water temperature, or growth rate into account [58]. In addition, feeding efficiency is also influenced by the type of farming facility as confined bodies of water, such as raceways or bags, allow for more efficient feeding practices and effluent management [59].

Replacing Ecosystem Services with Anthropogenic Processes at Farm Site

Traditional extensive aquaculture systems depend, to a large extent, on labor and natural energy inputs [3]. Solar energy inputs promote in-situ production utilizable by some farmed animals while tidal energy or other

natural watercourse flows provide means for water exchange. As for energy consumed in highly mechanized production systems, such as most intensive land-based systems, the energy for farm-site activities often originates from fuel as farm-sites typically lack access to alternative sources of energy. It is therefore recommended to consider the location characteristics of the farm-site before implementing artificial services. Farms situated in areas with high water turnover, i.e., in streams, tidal zones, or exposed coasts, may cause little or no impact on the local ecosystem. Farms situated in areas without such hydrodynamic conditions need to treat their wastewater to avoid negative impact on the environment or run as closed systems. It is, however, important to acknowledge that environmental impacts from farm release need to be analyzed from an ecosystem perspective, which implies considering additional pollution sources and more regional scale effects and thresholds.

LCA has limited capacity to predict the actual consequences of many of the estimated impact potentials [60]. It may be justifiable to have such an approach for the impact categories that are operational on a global scale, such as global warming potential or ozone depletion. For more regional consequences, however, it can be highly misleading to make comparisons of the impacts between two localities. To address this in a more justifiable manner, several country-specific factors, such as RECIPE, TRACI, EDIP2003, and LUCAS [61], have been developed and arguments have been raised for similar factors on regional scales [62].

Transmission of disease and parasites between wild and farmed stock and introduction of non-indigenous species are both major concerns associated with aquaculture that have yet have not been addressed by LCA methodology [63, 64]. Nor is the framework necessarily conducive to accommodating such interactions since it is necessary to be able to link the impact to the production of a functional unit following a clear and quantifiable cause-effect pathway. Both of these types of impacts have attracted much public attention and have been major incentives for closed farming facilities. Transmission of sea lice has, apart from having potentially detrimental effects on wild fish stocks, been estimated to account for 6% of the product cost in salmon farming [64]. Floating cages and net cultures allow for free movement of pathogens from farmed to wild stocks [64]. They also run an increased risk of large escape events of domesticated fish due to their vulnerability to extreme weather events, marine mammal interactions, failing infrastructure, and management errors. Such events can lead to the introduction of non-indigenous species as well as undermining the genetic fitness of wild stocks. It has been estimated that aquaculture is responsible for 16% of all introductions of non-indigenous species to European coastal waters, and further introductions are to be expected with changing climate [63].

The use of chemicals and antibiotics on farm sites is still only generally covered by existing impact categories. These practices can result in long-term effects such as antibiotic-resistant bacteria or other public health risks [10]. They may also lead to contaminated water sources and loss of biodiversity [10]. Shrimp farms are implicated most frequently for using large amounts of antibiotics to reduce stock losses. On several occasions, this has resulted in product recalls and import bans by the EU, Canada, and the USA [10]. The social consequences of this might be direct (e.g., lower water quality) or indirect, as import bans can seriously affect the financial viability of many farmers [65]. Even if LCA has the potential to account for such social and economic consequences, there is a lack of metrics to describe how to include socioeconomic indicators [28]. Overcoming the hurdles associated with the development of such impact categories would allow for better estimations of overall sustainability, including environmental, social, and economic variables [28]. However, it should be recognized that LCA is not necessarily conducive to accounting for the full spectrum of sustainability concerns. As such, it should be considered a complement to, rather than a replacement for, other metrics.

Discussion

As the number of LCA studies describing aquaculture systems increases, so too does our understanding of a broader suite of the environmental costs of aquaculture production. In some cases, it would appear that aquaculture may indeed provide an inexpensive and sustainable source of food and other products; however, this will depend on numerous factors including cultured species, production technology, and socioeconomic characteristics. To date, LCA research has helped to identify those aspects of the life cycle that contribute

disproportionately to environmental degradation, allowing for the identification of improvements opportunities. There is, however, always the danger of oversimplification where results get misinterpreted as a result of inaccurate data or where results are not put into their relevant context. LCA should therefore not be seen as an all-encompassing tool, but rather as a screening tool, which allows for the mapping of good practices. Additional environmental and socioeconomic analyses can thereafter be applied to strengthen assessment of sustainability.

As for advancements that can be made within the sector, the major challenge will be to find good sources of low impact feed inputs for fed aquaculture systems, especially for fish oil that currently drives the demand for wild marine resources [46]. This would, of course, ideally be combined with further advances in feed utilization by fish in culture. A shift toward organically produced crop inputs may also reduce the impacts of fed aquaculture, while bringing other benefits such as biodiversity improvements and superior soil quality [57, 66]. However, the choice of some resource intensive "organic" inputs can negate much of the life cycle environmental benefits associated with organic crop production [57]. Another alternative protein source is offal meal from fish processing. Tilapia, for example, has an offal yield of about 67% of live weight [59]. This does, however, increase the risk of disease transmission and/or recycling of environmental contaminants [53]. Moreover, the environmental costs of producing these materials from a life cycle perspective may be high [22]. Recently, there has been increased interest in the use of fish processing co-products for biofuel feedstock [67]. Conversion of high-quality protein into biofuels appears rather wasteful when the environmental burdens associated with producing certain high protein feed inputs are taken into account. It is clearly desirable to identify and implement optimal uses of high-quality protein toward the overarching sustainability objective. This must include, among other things, attention to the environmental dimensions of alternative protein production and use strategies. Since our ability to make informed decisions will be strongly influenced by the robustness of our models and the extent to which they actually reflect the environmental impacts associated with the products and systems of interest, methodological decisions such as choice of allocation criterion should be clearly communicated and defended in the context of each analysis.

Increasing trade flows of aquatic products from developing to developed countries highlights the need for more LCA work beyond production systems in the developed world. It also indicates that there are substantial opportunities for expansion of aquaculture in developed countries. Tyedmers et al. [2] points out that the USA only accounts for 1% of global aquaculture production, half of which is made up by channel catfish. Future developments may also to be expected within mariculture, as much recent effort has focused on the development of marine fin-fish hatcheries and offshore cages.

Impacts involved with on-site activities can more easily be avoided by selecting for better farm locations, use of renewable energy, improved utilization of ecosystem services, and farming of more tolerant species. One example of such a species is Pangasius catfish, which has reached high production levels in Vietnam over the last decade. This fish does not require aeration as it can utilize aerial respiration when the oxygen level drops. The farms also often utilize tidal floods for water exchange [20]. As for tilapia, the tolerance toward hypoxia and changes in pH is much higher than other species normally found in western aquaculture. This would, again, lower the inputs needed for maintaining water quality. Wastewater quality can also be improved by the use of settlement ponds and/or plant production to remove nutrients. Cultivation of plants such as *Azolla* spp. and duckweed within ponds can also enhance carbon fixation and be used as feed inputs [48, 68]. Duckweed may further reduce GHG emissions as it will shade the pond and thereby limit the ammonia volatilization rate [49]. Some of these feed inputs may, however, negatively influence the color and the taste of the final product, which makes them less suitable as feed inputs [48].

Converting to energy conserving practices will not only have environmental benefits, it can also improve the economic profitability of farms and reduce vulnerability to peaks in the price of oil. Lower intensity systems are also less sensitive to mechanical or infrastructure failures, such a black outs, which otherwise can cause mass mortality. This is especially important in developing countries where there is less access to spare parts and power failures are recurring events.

Open systems are, on the other hand, more vulnerable to other events such as algae blooms, pollution, and extreme weather events, which may cause the loss of an entire crop. Areas ravaged by extreme storm events, such as typhoons, may suffer from weeks of poor water quality as large quantities of sediments may lead to high turbidity for long periods of time.

More knowledge on the true carbon emissions associated with aquaculture is needed as there is increasing interest in its potential as a climate-friendly source for food and biofuels [68, 69]. LCA can play an essential part in the screening for sustainable farming practices and also provide information for the implementation of carbon credit schemes. This need is especially critical for developing countries, as this is where the majority of production occurs and exports are increasing. This will, however, pose a challenge as farming methods are highly diverse and data on farm practices are usually limited.

Also, some important environmental impacts from aquaculture are at present not quantifiable using the LCA framework, such as spread of diseases and parasites. These impacts have been attracting widespread public concerns and have influenced development of farming methods in many countries. The associated consequences could, for example, be accounted for as biotic resource use. Concerns associated with deforestation to produce agricultural land should also be further discussed, as it is only partially covered in current LCA practice and literature.

Future Directions

LCA provides a robust tool for dealing with an important subset of sustainability concerns, many of which have historically been overlooked in discussions of environmental management in aquaculture. However, it must be kept firmly in mind that decisions made during the analytical process strongly influence research outcomes.

It is, therefore, important to continue the discussion about such methodological decisions, including the kind of LCA framework applied (i.e., attributional versus consequential LCA), systems boundaries, and choice of allocation methods for LCAs of aquaculture production. In the least, it would be constructive for all practitioners to clearly communicate and defend all methodological choices, as they may ultimately send different signals to the industry and policy makers working with sustainability issues.

A more standardized methodology within the sector would certainly facilitate the advancement of the field. This could be achieved by better communications between major practitioners or by the development of a manual to guide the community toward one common framework. Even still, there will always be deviations from common practice as each study serves a unique purpose, stressing the need for more transparency.

Even though ongoing initiatives for developing the LCA framework exist, it is important to acknowledge that the present framework has limited ability to accommodate the other two pillars of sustainability, namely, social and economic impacts [28]. Thus, even if LCA provides a tool with great potential to guide the aquaculture industry toward more sustainable production, its framework needs to be reinforced by other analytical tools to capture a wider range of sustainability concerns. The need to include other tools alongside LCA has already been recognized and recent projects, such as the SEAT project (www.seatglobal.eu), include complementary tools to give a more holistic measurement of sustainability. Limitations aside, however, the rapid development of this sector, coupled with the diverse range of possible culture species and technologies, demands careful attention to environmental effects at all relevant scales. LCA can and should play an important role in guiding decisions oriented toward sustainability in aquaculture.

Definition of the Subject

This entry provides a detailed life cycle assessment (LCA) of combustion vs. landfilling of post-recycling municipal solid waste (MSW). LCA can be used to evaluate the environmental footprint of products, processes, and services. An LCA allows decision makers to compare products and processes through systematic evaluation of supply chains. LCA takes a "cradle-to-grave" approach, by including each stage of life for a given product or process, which includes the extraction of raw materials, transportation, manufacturing, distribution, use, and final disposal. LCA has been

widely utilized to analyze different solid waste management alternatives [1–9]. In the USA, 220 million Mg (1 Mg = 1 metric ton) of MSW was generated in 2009, of which only 32% was recycled, and 13% was combusted with energy recovery [10]. Despite resource conservation efforts, over 50% of the US MSW is discarded in landfills. This number is significantly higher than other countries such as Denmark, where only 4% of the MSW generated is disposed in landfills. The remaining 96% is recycled or combusted for energy recovery. There is an ongoing debate about the relative environmental merits of landfill gas to energy (LFGTE) vs. waste to energy (WTE). Application of LCA revealed that the relative emissions associated with both options are highly sensitive to the input data in the life cycle inventory (LCI).

Introduction

While per capita generation has been relatively constant for the past decade, the absolute amount of MSW generated is increasing due to population growth. In 2002, the US Environmental Protection Agency (US EPA) established the Resource Conservation Challenge to increase the nationwide recycling rate to 35%. The challenge encourages pollution prevention, resource conservation, efficient use of materials, and a materials management approach to waste management. Current recycling and composting rates in the USA have almost reached the 35% goal [10]. In addition, 13% of MSW is combusted in WTE facilities. The rest of the MSW, totaling 151 million Mg according to the US EPA, is disposed in landfills. Europe's solid waste management (SWM) policies also focus on the minimization of MSW disposal in landfills and maximization of the environmental benefits through material and energy conservation. For example, in Denmark, only 4% of MSW is disposed in landfills. Most of the Danish MSW (55%) is combusted, and the balance (42%) is recycled [11]. The US public generally perceives solid waste combustion as hazardous and toxic, a response to the poor environmental performance of incineration facilities in the 1980s and early 1990s, which lacked air pollution control systems (APCS). This concern was a motivation for the Clean Air Act (CAA) Amendment which required all WTE facilities in the US to have APCS installed [12]. In 2010, there were 86 WTE plants with continuous emission monitoring, operating in 24 states [13]. Each facility is required to submit the result of an annual stack test to measure performance and demonstrate compliance with regulations. These measures have alleviated much of the risk associated with WTE. Now with scientific concern about climate change and GHG emissions, it is a good time to revisit WTE and its role in GHG mitigation. For example: What are the net impacts of WTE, and how do these compare with alternatives such as landfilling without any landfill gas (LFG) collection, landfilling with LFG collection and then flaring, landfilling with LFG collection and then electricity production also called LFGTE? Further, as a source of energy, how do the GHG emissions from WTE compare with those of fossil fuels and nuclear power? LCA provides a means to answer these questions.

This chapter describes the calculation of LCI air emissions from WTE and compares the results with the LCI emissions from landfills with different LFG management options. Background information on LCI is presented in the next section, followed by a description of the system boundaries and design basis for the WTE LCI. The method used to calculate each emission factor and the amount of energy recovered is then described. Emission factors are reported on both a per Mg basis and per unit electricity generated. In addition, sensitivity of emission factors to various parameters such as efficiency of the electricity generation at the power plant, LFG collection efficiency, and waste composition is also investigated and presented along with the results.

Background on Life Cycle Assessment

The design of SWM strategies that are efficient with respect to material and energy conservation requires a site-specific evaluation of multiple SWM alternatives. For example, energy recovery in a WTE facility may represent an efficient way to recover the energy value of the materials while at the same time displacing fossil fuels. However, if the materials are recycled otherwise, this may reduce demand for energy in manufacturing. Thus, a thorough examination of the impacts of WTE facilities must include full life cycle impacts as well as comparison on the benefits of converting recyclables to

new products. Given these many complexities, life cycle models are essential for calculating the energy consumption and environmental emissions. Integrated life cycle models for SWM typically are comprised of modules that represent each unit process of a given solid waste system, including collection, separation, recycling, treatment, and landfill processes.

The goal of LCA is to evaluate the full environmental impacts of a process or product. The LCA is carried out in four phases: goal and scope definition, life cycle inventory, life cycle impact assessment and interpretation. In this chapter, the LCI concept is applied to MSW combustion. The essential feature of LCI methodology is an attempt to thoroughly consider all aspects of a process. In the context of MSW combustion, the LCI methodology requires estimation of both the direct emissions from a combustion facility that recovers energy and the avoided emissions at a power plant (including associated steps for fuel extraction and transportation). General information on LCI methodology as it can be applied to MSW management has been presented previously in [9].

System Boundaries of the WTE LCI

A LCI model for WTE developed by [14] is utilized to calculate the LCI-based emission factors presented in this entry. This model is a part of an integrated SWM life cycle model that has individual unit process models for collection, recycling, transfer, treatment, and disposal of MSW [4, 15]. The LCI-based emission factors for WTE include all the activities associated with the combustion of 1 Mg of MSW as it is received by the WTE facility. A typical mass-burn combustion facility with energy and ferrous metal recovery is assumed for the analysis. The facility is equipped with all necessary APCS to comply with the prevailing air quality regulations. The following APCS are assumed to be present in the facility: spray dryer absorbers for acid gas (i.e., SO_2 and NO_x) control, activated carbon injection for mercury control, injection of ammonia for NO_x control by conventional selective non-catalytic reduction, and a fabric filter for particulate matter (PM) control. The LCI emissions associated with collection, transfer, and separation of MSW and ash disposal are considered in separate unit process LCI models, which can be found in [15].

The LCI model for WTE can track 32 life cycle parameters, including energy consumption, CO_2, CO, NO_x, SO_2, total greenhouse gas equivalents (CO_2e), PM, CH_4, water pollutants and solid wastes associated with combustion of MSW as well as indirect burdens. The CO_2 emissions are represented in two forms: fossil and biogenic. The CO_2 released from anthropogenic activities such as burning fossil fuels or fossil-fuel derived products (e.g., plastics) for electricity generation and transportation are categorized as CO_2-fossil, while the CO_2 from biogenic materials (e.g., paper, food waste) released during combustion, or biodegradation in the case of landfills, is categorized as CO_2-biogenic. The CO_2e represents the summation of CO_2-biogenic, CO_2-fossil and CH_4 emissions, multiplied by their corresponding global warming potentials (GWP). The GWPs for CO_2-biogenic, CO_2-fossil and CH_4 are 0, 1 and 25, respectively [16].

The emission levels depend on waste composition, combustion process details, and the effectiveness of installed APCS. For example, the quantity of CO_2 emissions is composition dependent, whereas the quantity of criteria air pollutants and hazardous air pollutants depends primarily on flue gas treatment procedures. Generally, WTE plants in the USA do not generate wastewater, and the sludge generated from semidry or wet scrubbing is not included in this LCI. The WTE LCI model does not differentiate between bottom ash and fly ash. The quantity of total ash is a function of the materials combusted in the facility, the corresponding ash content, and the assumed uncombusted fractions of each material. The assumptions regarding MSW component characteristics are presented in Table 1. The amount of limestone and ammonia used in the APCS are also added to the total quantity of ash produced. The ash is then taken to an ash landfill for disposal. Another LCI model developed by [17] is used to track emissions associated with the disposal of ash.

The emissions associated with the production of limestone and ammonia for the APCS are included as indirect burdens in the LCI. The emissions associated with the construction of the facility are less than 1% of total LCI emissions occurring during the operation of the facility [18]. As a result, construction emissions were excluded from the results presented here. The steam generated in the WTE facility is converted to

electricity, which then contributes to baseload electricity generation within the regional electric grid. Thus, the supply of electricity from the WTE plant avoids emissions from conventional fossil fuel-fired power plants. These avoided emissions are calculated and included in the LCI as an emissions reduction. In addition, most WTE facilities recover ferrous metals from bottom ash. The LCI model takes into account the avoided emission from the manufacturing of iron and steel from raw materials due to ferrous recycling.

Life Cycle Inventory

Method to Generate Emission Factors Per Mg of Waste Item

The WTE LCI model generates emission factors per Mg of each waste item, which is the summation of emissions associated with (1) the combustion of MSW (while accounting for the emission controls), (2) the production and use of limestone and ammonia in the APCS, (3) offsets applied due to avoided regional grid emissions, (4) offsets applied due to ferrous recovery, and (5) emissions associated with ash disposal [14]:

$$\begin{aligned} LCI_WTE_{ij} = (&LCI_Stack_{ij} + LCI_Limestone_{ij} \\ &+ LCI_Ammonia_{ij} - LCI_GridEmissions_{ij} \\ &- LCI_FeOffsets_{ij} + LCI_Ash_{ij}) \quad \text{for all } i, j \end{aligned} \tag{1}$$

where LCI_WTE_{ij} is the LCI emission factor for pollutant i (g/Mg of waste item j); LCI_Stack_{ij} is the controlled stack gas emissions for pollutant i (g/Mg of waste item j); $LCI_Limestone_{ij}$ is the allocated emissions of pollutant i from the production and use of limestone in the scrubbers (g/Mg of waste item j); $LCI_Ammonia_{ij}$ is the allocated emissions of pollutant i from the production and use of ammonia (g/Mg of waste item j); $LCI_GridEmissions_{ij}$ is the allocated emissions of pollutant i associated with the avoided utility emissions (g/Mg of waste item j); $LCI_FeOffsets_{ij}$ is the emission offset for pollutant i per Mg of recycled ferrous material; and LCI_Ash_{ij} is the emissions of pollutant i associated with the disposal of ash from WTE facility (g/Mg of waste item j).

The magnitude of the emission factors thus is a function of heat rate (Btu/kWh) (i.e., the amount of energy input in Btu required to generate 1 kWh of electrical energy), waste composition, and the pollutant removal efficiency of the APCS. The characteristics of MSW assumed for this study are given in Table 1. The composition and amount of MSW determines the total electricity generated, which affects the total avoided emissions from the grid. Avoided grid emissions are allocated based on the energy content of the individual waste item. The emissions remaining after APCS treatment are allocated equally among different waste categories. Facility design assumptions are given in Table 2.

The CO_2 emissions are calculated using a stoichiometric equation for combustion given the quantity, moisture, and ultimate analysis of individual waste items. The emission rates for criteria air pollutants were calculated using field level stack gas concentrations (including the controls) and resultant flue gas volumes [14]. The performance data on WTE plants in the USA reveal that all the facilities' stack gas concentrations are either well below or within the regulatory limits [12]. The WTE LCI model can use either the regulatory concentration limits or average stack gas concentration limits to calculate the emission factors. Table 3 presents these input concentration limits. The results presented here are calculated using the regulatory limits; however, sensitivity analysis is conducted to demonstrate the effects of changes in concentration limits on emission factors.

Life Cycle Comparison of Waste-to-Energy to Sanitary Landfill. Table 2 Summary of major parameters characterizing a combustion facility

Parameter	Units	Assumptions
Lifetime	Years	20
Capacity factor		0.91
Heat rate	Btu/kWh	18,000
Conversion efficiency	%	18%
Limestone usage in the APCS	Mg/Mg of MSW	0.007055
Ammonia usage in the APCS	Mg/Mg of MSW	0.0015
Ferrous ash recovery rate	%	90
Unburned waste	%	5

[b]See Ref [35]

The WTE LCI accounts for all energy and material recovery activities. The WTE LCI model calculates the total electricity generated per unit mass of waste item based on the assumed heating value, ash content of each waste item, and heat rate of the WTE facility. The electricity generated at the WTE facility is fed into the regional grid to help meet part of the baseload demand. As a result, electricity generation from conventional sources is avoided, leading to a proportional decrease in emissions.

A separate LCI model for the electric sector was developed to calculate emission factors per unit electricity generated in a given region in the USA or the national grid [19]. Each of the electric grid regions in the North American Electric Reliability Council (NERC), an average national grid, or a user-defined grid can be defined in the model through input of fuel mixes. The fuel mixes for NERC regions and the national average are taken from the US EPA's eGRID database [20] and presented in Table 4. The LCI model for the electric sector concurrently calculates emission factors for each of the electric generating units (EGUs) powered by coal, natural gas, oil, biomass, hydroelectric, and nuclear. The factors include both the operating emissions with post-combustion APCS and precombustion emissions including the extraction, processing, and transportation of fuel. The precombustion LCI data for each of the fuels running the EGUs in the grid was obtained from the National Renewable Energy Laboratory (NREL) LCI database [21–24]. The database reports emissions associated with the extraction, processing, and transportation of fuel. These data were reported on a unit mass of fuel bases [21–24]; when converted to emissions per unit of electricity generated, the magnitude of the resultant emissions factor is inversely proportional to the efficiency of the power plant. The efficiency of the EGUs and the corresponding emission factors used in this analysis are presented in Table 5. The results of this analysis include offsets for coal-fired power plants in the SERC regional grid. The SERC grid represents 27% of US electricity generation, and the fuel mix in the SERC region roughly matches the fuel mix of the US national average grid. The emission factors for the SERC regional grid are summarized in Table 6.

Most WTE facilities recover up to 90% of the ferrous materials from the bottom ash. The recycled ferrous material replaces iron ore and other raw materials in the production of steel. As a result, emissions due to steel manufacturing from virgin materials are avoided. In terms of greenhouse gas emissions, 1.05 Mg CO_2e is avoided per Mg of recycled ferrous material as a result of recovery activities. The complete set of LCI emissions is presented in Table 7.

The WTE LCI emission factors per Mg of MSW item are summarized in Tables 8 and 9. Table 8 presents the combustion-related emission factors associated with WTE facilities. These factors exclude offsets associated with electricity generation and ferrous recycling as well as the burdens associated with the use of limestone and ammonia in the facility. Table 9 presents the LCI emissions from WTE facilities that include stack gas emissions, emissions associated with limestone and ammonia production, and offsets associated with the electricity generation in coal-fueled EGUs in the SERC region. Table 10 presents the emissions associated with the disposal of ash from the WTE facility. From these tables, the LCI emission factors for WTE are derived using Eq. 1.

Solid waste	g/Mg	−2.53E + 05
Energy	MBTU/Mg	−1.89E + 02

[a]Negative values indicate the magnitude of emission avoided due to remanufacturing activities

MSW. In addition, the functional unit of LCI is shifted from 1 Mg of waste item to 1 MWh of electricity generated. In order to facilitate a side-by-side comparison of WTE with LFGTE and other electricity generation options, the emission offsets associated with generation of electricity via WTE is excluded from the factors. The emissions per MWh of electricity generated are then calculated using the following equation:

$$WTE_MWh_i = \sum_j \{ (LCI_Stack_{ij} + LCI_Limestone_{ij} + LCI_Ammonia_{ij} + LCI_Ash_{ij}) \times Mass_j \} \div Elec \text{ for all } i \quad (2)$$

where WTE_MWh_i is the LCI emission factor for pollutant i (g/MWh); LCI_Stack_{ij} is the controlled stack gas emissions for pollutant i (g/Mg of waste item j); $LCI_Limestone_{ij}$ is the allocated emissions of pollutant i from the production and use of limestone in the scrubbers (g/Mg of waste item j); $LCI_Ammonia_{ij}$ is the allocated emissions of pollutant i from the production and use of ammonia (g/Mg of waste item j); LCI_Ash_{ij} is the allocated emissions of pollutant i from the disposal of ash (g/Mg of waste item j); $Mass_j$ is the amount of each waste item j processed in the facility (obtained from Table 1); and $Elec$ is the total electricity generated from MSW processed in the facility (MWh) and calculated as follows:

$$Elec = \left(\sum_j HeatingValue_j * Mass_j \right) * \frac{\frac{2000 \frac{\text{lb}}{\text{ton}}}{1000 \frac{\text{kWh}}{\text{MWh}}}}{HeatRate} \quad (3)$$

where $HeatingValue_j$ is the heating value of item j (Btu/lb) and $HeatRate$ is the thermal efficiency of the WTE facility (Btu/kWh). These emission factors exclude the emission offsets associated with generation of electricity.

Method to Generate Emission Factors for Landfill Gas to Energy

The total LCI emissions from landfills are the summation of the emissions resulting from (1) the site preparation, operation, and post-closure operation of a landfill, (2) the decay of the waste under anaerobic

Life Cycle Comparison of Waste-to-Energy to Sanitary Landfill. Table 8 LCI emissions from WTE (controlled emissions only) (g pollutant/Mg of waste component)

Life Cycle Comparison of Waste-to-Energy to Sanitary Landfill. Table 11 Inputs to landfill process model

During	LFG collection system efficiency[a] (%)	Oxidation rate (%)
Venting	0	15
First year of gas collection[b]	50	15
Second year of gas collection	70	15
Third year onward of gas collection	80	15

[a]We assumed efficiency of the collection system based on the year of the operation and the ranges stated in [31]
[b]Gas collection can start anytime during the operation of the landfill. In this analysis, two scenarios were considered. In the first scenario, gas collection starts at the second year of the operation, and in the second one, the gas collection starts at the fourth year of the operation

conditions, (3) the equipment utilized during landfill operations and landfill gas management operations, (4) the production of diesel required to operate the vehicles at the site, and (5) the treatment of leachate [17, 25]. The production of LFG was calculated using a first-order decay equation for a time horizon of 100 years and the measured methane yield from each individual waste component [17, 26]. The LCI model also requires the quantity and composition of the waste disposed, LFG collection efficiency (Table 11), annual LFG management schedule, oxidation rate (15%), emission factors for combustion by-products from LFG control devices, and the emission factors for equipment used on site during the site preparation and operation of a landfill. The LFG collection efficiency can be varied annually. The emission factors are calculated under the following scenario assumptions:

1. A regional landfill subject to CAA is considered.
2. A single cell in the regional landfill is modeled.
3. Waste is initially placed in the new cell in Year 0.
4. The landfill already has a LFG collection network in place.
5. An internal combustion engine (ICE) is utilized to generate electricity.
6. The offline time that is required for the routine maintenance of the ICE is not considered.
7. The LFG control devices are assumed to have a lifetime of 15 years.
8. The LFG will be collected and controlled until Year 65. This assumption is based on a typical landfill with an average operating lifetime of 20 years in which LFG production decreases significantly after about 60 years from initial waste placement. The LFG production is based on the use of a first-order decay equation.

In practice, the timing of LFG-related operations such as the installation of the gas capture system, start of gas capture, and the installation of energy recovery equipment exhibits significant variation that will influence the total emissions from an individual landfill. To capture these variations, several different LFG management schemes were tested. An average or typical LFG management scheme would vary significantly from one location to another. Kaplan et al. [27] enlist a variety of scenarios for comparison. Here, the WTE LCI emission factors were compared in detail against three LFG LCI scenarios, and the sensitivities around various operational assumptions are accounted and presented as lower and upper bounds. The first scenario assumes 100% venting of LFG for the entire life of the landfill. The second assumes venting of the LFG for the first 4 years and then flaring of the LFG until Year 65. The third scenario represents an LFG energy recovery scenario: The LFG is vented for the first 4 years followed by the installation of an LFG collection system in the landfill. The recovered LFG is flared for 2 years, and subsequently combusted in an ICE for electricity generation for 30 year, then flared until Year 65. In practice, this energy recovery period could last anywhere from 10 to 60 years. The extent of this time period depends on the site characteristics such as flow rate and the quality of the captured methane gas, regional climate, and economic feasibility. Table 12 presents the LCI emission factors per Mg of MSW components for the LFGTE case with 30 years of electricity generation through the use of an ICE. These emission factors include offsets associated with the generation of electricity from coal-powered EGUs in the SERC region.

In addition, LCI emission factors per MWh of electricity generated were calculated for LFGTE scenarios. A procedure similar to one detailed for WTE is followed. The reader may refer to [27] for details on

the calculations of the LCI emission factors. These emission factors, similar to WTE counterparts, exclude the emission offsets associated with the generation of electricity.

Results and Discussion

The LCI emission factors for WTE were generated on a per Mg of MSW item and compared to LCI emission factors for LFGTE scenarios. Table 13 summarizes the CO_2e emission factors for major waste items such as paper, yard waste, and plastics sent to either WTE or LFGTE. The CO_2e emission factors for WTE include all the components presented in Eq. (1). All of the biogenic waste items such as grass, leaves, cardboard, and food waste result in avoided emissions when combusted in a WTE facility. When biogenic items are disposed in landfills—even with energy recovery—the CO_2e emission factors for those items are higher than the factors for fossil-based waste items such as plastics, mainly because organic materials decompose in the landfill under anaerobic conditions, which results in methane emissions. Methane being a more potent greenhouse gas than CO_2 leads to higher CO_2e emission factors. Plastics, on the other hand, do not decompose in landfills. However, their higher carbon content translates to a higher energy content per unit mass, which results in higher CO_2e emissions when combusted in a WTE facility. The average composition of MSW as discarded by weight was calculated to be 77% biogenic- and 23% fossil-based [28]. Based on the average composition of discarded MSW presented in Table 1, average CO_2e factors were calculated. A WTE facility receiving the discarded portion of MSW resulted in avoided or negative emissions of 345 kg CO_2e/Mg of MSW, whereas the emissions from LFGTE were 219 kg of CO_2e/Mg of MSW, which includes the electricity generation offsets.

When waste is buried in a landfill, some of the biogenic material does not degrade, and this material is said to be stored. While carbon storage was not included in this analysis, it could have a significant impact on the results. For example, Staley and Barlaz (2009) report carbon storage factors of about 0.13 kg C/kg dry refuse [29]. At a moisture content of 20%, this translates to 381 kg CO_2e/Mg of wet refuse. This value would be subtracted from the landfill LCI result of 219 kg of CO_2e/Mg of MSW to obtain an LCI emission factor that accounts for the carbon sequestration.

The LCI emissions were calculated per MWh of electricity generated and compared to the LCI-based emission factors for LFGTE. A parametric sensitivity analysis was conducted on the LCI emission factors to establish lower and upper bounds. We hypothesize that the variations in the MSW composition and electricity conversion efficiency of the WTE facility could have significant effects on the LCI emission factors. The sensitivity of emission factors to biogenic- vs. fossil-based waste fraction was also determined. Two compositions (one with 100% biogenic-based waste and another with 100% fossil-based waste) were used to generate the emission factors. In addition, the conversion efficiency of the WTE facility was varied from 15% to 30%. A summary of this analysis is presented in Table 14. For LFG scenarios, the LCI emission factors were varied by changing oxidation rates and analyzing various LFG management scenarios. The LCI emission factors for the conventional EGUs are recalculated while the conversion efficiencies are varied. The lower and upper bounds on the LCI emission factors are established. The results of this analysis are presented in the figures as lower and upper bounds; however, for more details on the assumptions and the full sensitivity

analysis, the reader should refer to Kaplan et al. [27]. In addition, the reader should recognize that the LCI emission factors for WTE and LFGTE per MWh of electricity generated do not include the offsets associated with the avoided electricity generation from the grid.

Figure 1 presents the emission factors for total CO_2e per MWh of electricity generated for landfills,

Life Cycle Comparison of Waste-to-Energy to Sanitary Landfill. Figure 1
Comparison of carbon dioxide equivalents for LFGTE, WTE, and conventional EGUs (Note that the Flare and LFGTE options have same CO_2e, this due to the fact that emission factors per MWh do not include offsets associated with the generation of electricity from LFG.)

WTE, coal, natural gas, oil, and nuclear power plants. The WTE scenarios result in less CO_2e emissions than the LFG scenarios. The vented methane in the early years of the landfill operation is the main contributor to the higher CO_2e emissions. The CO_2e emissions from WTE ranged from 0.02 Mg of CO_2e/MWh to 1.5 Mg of CO_2e/MWh, where the low end of the range represents high efficiency and MSW composition with 100% biogenic waste while the high end of the range represents emission factors calculated using MSW composition consisting of 100% fossil-based waste items. However, the CO_2e emissions from WTE—even the ones based on 100% fossil-based waste—are still lower than the most aggressive LFGTE scenario whose CO_2e emissions are 2.3 Mg of CO_2e/MWh. Figure 2 provides a closer look at the CO_2e emission factors for WTE and conventional EGUs and distinguishes between precombustion and combustion-related emissions. The average CO_2e emissions for WTE are 0.56 Mg of CO_2e/MWh, resulting in lower emissions than coal and oil; however, natural gas and nuclear have still lower greenhouse gas emissions than WTE.

SO_2 emissions from WTE facilities occur during the combustion process and are controlled via wet or dry scrubbers. The use of LFG control during operation, closure, and post-closure of the landfill as well as the treatment of leachate contributes to the SO_2 emissions from landfills. Figure 3 presents SO_2 emission factors for WTE, LFG scenarios and conventional EGUs. Overall, the SO_2 emissions resulting from the LFGTE and WTE alternatives are approximately ten times lower than the SO_2 emissions resulting from coal- and oil-fired power plants with flue gas controls. The SO_2 emissions for WTE ranged from 140 to 730 g/MWh, and for LFGTE it ranged from 430 to 900 g/MWh. In a coal-fired power plant, average SO_2 emissions were 6,900 g/MWh. Note that the majority of the SO_2 emissions from natural gas are attributed to the processing of natural gas rather than the combustion of the natural gas for electricity-generating purposes.

During the combustion process, NO_x emissions result from two different oxidation mechanisms. First, a reaction referred to as "thermal NO_x" occurs between nitrogen in the combustion air and excess oxygen at elevated temperatures. A second reaction referred to as

Life Cycle Comparison of Waste-to-Energy to Sanitary Landfill. Figure 2
Comparison of carbon dioxide equivalents for WTE and conventional EGUs

Life Cycle Comparison of Waste-to-Energy to Sanitary Landfill. Figure 3
Comparison of sulfur dioxide emissions for LFGTE, WTE, and conventional EGUs

"fuel NO_x" represents the oxidation of nitrogen that is chemically bound in the fuel. For most coal-fired EGUs, thermal NO_x typically represents about 25%, and fuel NO_x represents about 75% of the total NO_x formed. Figure 4 presents NO_x emission factors for WTE, LFGTE, and conventional EGUs. The NO_x emissions for WTE alternatives ranged from 810 to 1,800 g/MWh, and for LFGTE, NO_x emissions ranged from 2,100 to

Life Cycle Comparison of Waste-to-Energy to Sanitary Landfill. Figure 4
Comparison of nitrogen oxides emissions for LFGTE, WTE, and conventional EGUs

3,000 g/MWh. In a coal-fired power plant, average NO_x emissions are 3,700 g/MWh. The emission factors for other criteria pollutants are also calculated. Besides CO and HCl emissions, the emission factors for all LFGTE and WTE cases are lower than the ones for the coal-fired generators [27].

In addition, the impact of WTE within the larger energy system is evaluated. Hypothetically, if 166 million Mg of MSW is discarded in regional landfills with energy recovery, on average roughly 10 TWh or 65 kWh/Mg of MSW of electricity can be generated, whereas a WTE facility can generate on average roughly 100 TWh or 600 kWh/Mg of MSW of electricity with the same amount of MSW. WTE can generate an order of magnitude more electricity than LFGTE given the same amount of waste. LFGTE projects would result in significantly lower electricity generation because only the biodegradable portion of the MSW contributes to LFG generation, and there are significant inefficiencies in the gas collection system that affect the quantity and quality of the LFG.

Moreover, if all post-recycling MSW (i.e., excluding recycled and composted portions) is utilized for electricity generation, the WTE alternative could yield a generation capacity of 14,000 MW, which could potentially replace ~4.5% of the 313,000 MW of current coal-fired generation capacity [30]. A significant portion of this capacity could be achieved through centralized facilities where waste is transported from greater distances. The transportation of waste could result in additional environmental burdens, and there are clearly limitations in accessing all discarded MSW in the nation. Wanichpongpan et al. [8] studied the LFGTE option for Thailand and found that large centralized landfills with energy recovery performed much better in terms of cost and GHG emissions than small, localized landfills despite the increased burdens associated with transportation [8].

The landfill emission factors include the decay of MSW over 100 years, whereas emissions from WTE and conventional electricity-generating technologies are instantaneous. The operation and decomposition of waste in landfills continues beyond the monitoring phases for an indefinite period of time. Reliably quantifying the landfill gas collection efficiency is difficult due to the ever-changing nature of landfills, number of decades that emissions are generated, and changes over time in landfill design and operation, including waste quantity and composition. Landfills are an area source, which makes emissions more difficult to monitor.

In a recent release of updated emission factors for landfill gas emissions, data were available for less than 5% of active municipal landfills [31]. Across the USA, there are major differences in how landfills are designed and operated, which further complicates the development of reliable emission factors. This is why a range of alternative scenarios is therefore evaluated with plausible yet somewhat optimistic assumptions for LFG control. For WTE facilities, there is less variability in the design and operation. In addition, the US EPA has data for all the operating WTE facilities as a result of CAA requirements for annual stack testing for pollutants of concern, including dioxin/furan, Cd, Pb, Hg, PM, and HCl. In addition, data are available for SO_2, NO_x, and CO from continuous emissions monitoring. As a result, the higher quality and availability of WTE data make estimation of emission factors less uncertain compared to LFGTE.

Conclusions and Future Directions

Despite increased recycling efforts, US population growth will ensure that the mass of MSW discarded in landfills will remain significant. Discarded MSW is a viable energy source for electricity generation in a carbon-constrained world. One notable difference between LFGTE and WTE is that the latter is capable of producing an order of magnitude more electricity from the same mass of waste. If the goal is greenhouse gas reduction, then WTE should be considered as an option under state and US renewable energy policies. In addition, LFTGE scenarios had on average higher NO_x, SO_2, and PM emissions than WTE. However, HCl emissions from WTE are significantly higher than the LFGTE scenarios.

This analysis does not address location-specific issues such as local air quality concerns. In cases where the remanufacturing and electricity generation offsets occur in locations different from the location of the WTE facility, the direct emissions from WTE could reduce local air quality. For example, if a WTE facility is located in an electric grid with a high penetration of renewable and nuclear, then WTE could result in an increase of CO_2e, NO_x, SO_x, and PM emissions. Future work to account for the geographic and temporal distribution of emissions would yield valuable insight into the life cycle performance and impact of WTE and LFGTE.

Glossary

Bedstead barrier A type of pedestrian-light rail crossing control device whose design prevents a pedestrian from walking straight onto the tracks by forcing them to make one or more turns immediately ahead of the tracks.

Channelization device A physical element that limits pedestrian movements to within the preferred pathway and that guides pedestrians to cross the LRT tracks at the designated crossing location.

Dynamic envelope The clearance on either side of a light rail vehicle required for the overhang resulting from any combination of loading, lateral motion, or suspension failure.

Flashing light signal assembly A warning device consisting of two red signal indications arranged horizontally that are activated to flash alternately when a light rail vehicle is approaching or present at a highway-rail at-grade crossing.

Light rail transit (LRT) A mode of transit service (also called streetcar, tramway, or trolley) operating passenger rail cars singly (or in short, usually two-car or three-car, trains) on fixed rails in right-of-way that is often separated from other traffic for part or much of the way.

Light rail vehicles (LRVs) Vehicles typically driven electrically with power being drawn from an overhead electric line via a trolley or a pantograph driven by an operator on board the vehicle and may have either high platform loading or low-level boarding using steps.

Off-quadrant The location at a light rail crossing, from the perspective of an approaching motorist, on the far side of the tracks and same side of the roadway. Warning devices for pedestrians at highway-rail crossings are typically absent in the off-quadrant.

Pavement markings Markings set into the surface of, applied upon, or attached to the pavement for the purpose of regulating, warning, or guiding traffic.

Pedestrian A person who travels on foot or who uses assistive devices, such as a wheelchair, for mobility.

Pedestrian automatic gate A type automatic gate at a highway-rail at-grade crossing that descends when activated by a light rail vehicle blocking the pedestrian path. The gate is typically delineated with red and white diagonal bars along its length and may include one small red light at the tip, which is illuminated when the gate is activated.

Pedestrian-light rail at-grade crossing The general area where a pedestrian pathway and a light rail vehicle cross at the same level, within which are included the light rail tracks, pathway, design features, and traffic control devices for those traversing the area.

Positive control device An element that provides a temporary or permanent physical barrier between the light rail tracks and locations where pedestrians can safely queue.

Public transportation (also called transit, public transit, or mass transit) Transportation by a conveyance that provides regular and continuing general or special transportation to the public, but not including school buses, charter, or sightseeing service.

Right-of-way (r-o-w) A strip of land devoted to light rail transportation purposes.

Traffic control devices All signs, signals, markings, and other devices used to regulate, warn, or guide motor vehicle, pedestrian, or bicycle traffic.

Swing gate A self-closing, non-locked, fence-type gate designed to swing open away from the track area and return to the closed position upon release.

Z-crossing A type of pedestrian-light rail crossing control device whose design forces a pedestrian to make a 90-degree turn and walk parallel to and facing oncoming light rail vehicles immediately ahead of the tracks.

Definition of the Subject

Descendants of the streetcar, light rail vehicles (LRVs) have their own distinct characteristics, including a broad range of operating environments (both on-street and in semi-exclusive or exclusive rights-of-way) and a wide extent of typical operating speeds (from 15 to 60 mph or 10 to 40 km/h). This flexibility, coupled with passenger attraction and capacity of the vehicles, has made light rail an increasingly viable public transportation option.

Accommodating light rail transit (LRT) in these multiple environments while maintaining or improving safety has led transportation planners and engineers to utilize a variety of innovative traffic control practices. These practices are used to manage conflicting movements with LRVs and to provide motorists, as well as pedestrians and bicyclists with better information upon which to base their decisions and have evolved over time in response to changes in the way that LRVs operate (higher speeds, more silent operation) and pedestrians behave (increased inattentiveness and more distractions). Since increased LRT safety is a worldwide need, traffic engineers and transportation planners in the United States and Europe have implemented and adjusted over the years a number of practices to minimize conflicts between LRVs and pedestrians.

This entry examines and describes the observations resulting from the author's research and firsthand experience in traffic engineering practices in the United States and Europe related to solving LRT conflicts with pedestrians. Those practices and traffic control devices that are most innovative and with the greatest potential for implementation in new or expanding LRT systems are graphically identified.

Introduction

A key strength of LRT is its ability to integrate well into an urban environment sharing the public right-of-way with motorists, bicyclists, and pedestrians. It is this characteristic that makes LRT successful in those urban corridors where a high-capacity mode of transportation is required to operate well in both an exclusive and a shared right-of-way. Although LRT is an inherently safe mode of transportation, accidents sometimes do occur, negatively affecting not only the parties involved in the accident, but also the entire operation of the LRT system and the reputation of the transit property. Furthermore, safety concerns, particularly with pedestrians, are always a subject of great debate between residents and transit planning agencies, in those communities where a new LRT system or an LRT line extension is being proposed.

The interactions between pedestrians and LRVs are substantially different from those between motorists and LRVs. In general, motorists tend to be more aware of their environment, while pedestrians, traveling in the relatively safe venue of protected sidewalk areas, do not routinely share the same continuous attentive edge.

When crossing the travel path of motor vehicles or LRVs, pedestrians are supposed to shift their attention

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Table 3 Possible solutions to observed pedestrian conflicts

Situation	Possible solution
Low level of pedestrian awareness	• Install LRV-activated signs and signals • Install LRV-specific passive signage at pedestrian eye level
Poor definition of pedestrian pathways	• Delineate dynamic envelope by contrasting pavement color and/or texture or paint • Construct physical barriers (fence, bollards with chains, landscape)
Cross-street access	• Provide adequate storage/queuing/refuge space • Install positive pedestrian control devices (automatic gates, swing gates, bedstead barriers, or Z-crossings)

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 1
LRV-activated internally illuminated warning sign (urban environment, median operation) Salt Lake City (Utah)

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 2
LRV-activated internally illuminated warning sign (urban environment, median operation) Valencia (Spain)

to a similar state of awareness as that exhibited by motorists or LRV operators. However, this shift does not always occur. Pedestrian inattentiveness is exacerbated when interacting with modern LRVs, which are nearly silent. Moreover, unlike motor vehicles, LRVs cannot swerve or stop quickly enough to compensate for pedestrians who are errant or disobedient of traffic control devices.

According to past research conducted by the author [1], incidents between pedestrians and LRVs are the least prevalent type of LRT-related collisions, representing approximately 10% of the total, but are the most severe and account for at least 50% of all fatalities resulting from such incidents. Additional research conducted for Transit Cooperative Research Board [2] further validated this finding.

Table 1 summarizes the total number of collisions with injuries and fatalities that have occurred at five LRT systems operating in the Western United States (Los Angeles, Portland, San Francisco, and Santa Clara) over the past few years. According to Table 1, more than three fourths of those involved in a pedestrian collision with an LRV are killed, compared to less than one fifth of those involved in a motor vehicle collision.

Similar, more extensive, geographical data provides similar conclusions. Table 2 presents the aggregate number of collisions by type that have occurred at

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 3
LRV-activated internally illuminated warning sign (urban environment, median operation) Bilbao (Spain)

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 4
LRV-activated internally illuminated warning sign with directional arrow (urban environment, median operation) Portland (Oregon)

most of the LRT systems in the United States from 2002 to 2007.

According to Table 2, LRV collisions with pedestrians represent approximately one fifth of the total but result in about two thirds of all fatalities resulting from those collisions. Also according to Table 2, an average of three persons are killed for every ten that are involved in a pedestrian collision with an LRV, as opposed to three persons killed for every 100 that are involved in a motor vehicle collision with an LRV. It is clear that finding an effective means of addressing and minimizing pedestrian-LRV collisions is critically important to the operations of LRT systems in the United States and abroad.

The interactions between pedestrians and LRVs are substantially different from those between motorists and LRVs. In general, motorists tend to be more aware of their environment, while pedestrians, traveling in the relatively safe venue of protected sidewalk areas, do not routinely share the same continuous attentive edge. Moreover, unlike motor vehicles, LRVs cannot swerve or stop quickly enough to compensate for pedestrians who are errant or disobedient of traffic control devices.

Possible strategies to minimize LRV/pedestrian conflicts are summarized in Table 3. These solutions address the types of situations identified above, and

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 5

underscore the need for establishing a set of principles and guidelines to achieve greater uniformity and consistency in implementing a safer LRT system.

The following sections of this entry provide a summary of innovative pedestrian control designs and practices that have been applied successfully to light rail system in the United States and Europe to address the types of conflicting motor vehicle and pedestrian movements with LRVs described above.

Pedestrian Conflicts

The design of a pedestrian-light rail at-grade crossing is only effective if pedestrians actually cross at the designated point by taking a path that allows them clear observation of the warning devices. Devices to control pedestrian travel across LRT tracks and warn about the presence or approach of an LRV can be grouped under three major categories [3]:

- Regulatory and warning devices (both passive and active)
- Delineation markings
- Positive control devices

This section describes some of the most innovative traffic control devices included under each category and provides graphic examples of their application at several LRT systems in the United States and Europe.

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 8
Two-way LRV warning sign with LRV symbol at an unsignalized crossing (urban environment, median operation) Bordeaux (France)

Regulatory and Warning Devices

Pedestrian crossing regulatory and warning devices include signs, pedestrian signals, flashing light signals, and audio devices. Signs used at LRT crossings are typically fixed standard signs, such as the railroad cross buck or the LRV symbol, or LRV-activated internally illuminated depicting words or graphic symbols. LRV-activated internally illuminated signs warn pedestrians of the increased risk associated with violating the crossing in the presence of an LRV. Figure 1 shows an example of an LRV-activated internally illuminated warning sign in Salt Lake City, used in combination with a pedestrian traffic signal. Figures 2 and 3 show similar internally illuminated signs in Valencia and Bilbao, depicting two variations of the international LRT crossing warning sign. These signs are typically installed where substantial pedestrian presence is expected or where additional information is needed due to complicated track or pedestrian crossing geometry.

Figure 4 shows an innovative internally illuminated sign in Portland depicting a side view of an LRV plus an arrow representing its direction of travel. LRV-activated internally illuminated signs are also used to warn

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 9
LRV-activated pedestrian signal (urban environment, pedestrian mall operation) Bordeaux (France)

pedestrians of additional LRVs approaching the crossing. Figure 5 shows the use of an LRV-activated internally illuminated SECOND TRAIN APPROACHING sign in San Jose, used in combination with a conventional flashing light signal assembly.

Supplemental warning plaques are also used extensively in United States and European cities evaluated in this paper. Figure 6 shows an example of a supplemental plaque used in combination with a pedestrian traffic signal head and an LRV-activated internally illuminated warning sign in San Francisco. Figure 7 shows a similar example used in the Barcelona LRT system, while Fig. 8 shows an installation in Bordeaux where the plaque is combined with an LRV warning sign at a pedestrian-only crossing. The intent of the signs and plaques is to clearly alert pedestrians about the possibility of LRVs approaching the crossings from both sides, and are typically installed at all pedestrian crossings.

Pedestrian crosswalk signals in most cities are similar to those installed at non-LRV crosswalks, with internally illuminated heads depicting the pedestrian WALK and DON'T WALK symbols. The city of Bordeaux, however, has installed LRV-specific

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 11
Pedestrian-LRV crossing delineation (urban environment, separate r-o-w) Dallas (Texas)

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 12
LRV dynamic envelope delineation (urban environment, median operation) Barcelona (Spain)

regulatory signals at key locations with heavy pedestrian usage, such as the pedestrian mall in the old town area (Fig. 9), to emphasize the impending arrival of a train and raise the pedestrian awareness about the prohibition to cross the street. The signal is normally blanked out and becomes activated by the approaching LRV.

Flashing red light signals used at pedestrian-LRV crossings have the same design and type of operation as those used in conventional highway-rail grade crossings, consisting of two red light units mounted on a horizontal line flashing alternately to indicate the approach or presence of an LRV. Figure 10 shows a pedestrian flashing red light signal assembly in San Jose, used in combination with an LRV warning sign and a supplemental plaque.

Delineation Markings

Delineation markings direct pedestrians to cross LRT tracks at a designated location. Pedestrian path delineation can be accomplished with line striping, differential pavement color or texture, contrasting surface materials or landscaping. Delineation is also used to mark the edge of the dynamic envelope of the LRV, that is, the clearance on either side of an LRV required for the overhang resulting from any combination of

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 13
LRV dynamic envelope delineation (urban environment, median operation) Bilbao (Spain)

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 14
LRV directional striping on a one-way track (urban environment, median operation) Barcelona (Spain)

loading, lateral motion, or suspension failure. Figure 11 shows a combination of line striping, contrasting color and differential pavement texture to delineate a pedestrian crossing in Dallas. Figures 12 and 13 depict a similar combination found in Barcelona and Bilbao, respectively, used to delineate the LRV dynamic envelope.

In addition to the dynamic envelope delineations shown in Fig. 12, arrow striping indicating the direction that LRVs typically traverse the crossing is also used extensively in Barcelona at all pedestrian crossings to warn pedestrians and help them look in the most appropriate direction (the opposite from where the arrow is pointing) before they walk onto the track area. The arrow in combination with the LRV symbol is striped between the two rails for a given LRV direction immediately downstream of the pedestrian pathway. A single arrow is used where LRVs typically operate in a single direction (Fig. 14), while two arrows are used when LRVs typically operate two-way in a single track (Fig. 15).

As an alternative to the previous European markings, LRT systems in the United States, such as those in Salt Lake City and San Francisco, have implemented pavement markings at the crosswalk edge with the word LOOK and two arrow heads pointing both ways, either adjacent to the tracks or on the sidewalk, as shown in Figs. 16 and 17.

Positive Control Devices

Positive control devices provide a physical barrier between the outer edge of the LRV dynamic envelope and the area where it is safe for pedestrians to congregate. These devices can be fixed or moveable.

Fixed barriers are used to restrict pedestrian movements as they approach an LRT crossing and lead them toward a designated crossing location. They include fencing, railing, bollards, and chains or wire strung between posts. Fixed barriers, such as those shown in Fig. 18 for the Dallas LRT system, are used to reinforce delineation markings and to increase awareness of the potential presence of an LRV at those locations where a more strict control of pedestrian flows approaching a crossing may be necessary for safety considerations.

Fixed barriers are also used to configure pedestrian-only crossings of the LRT tracks. The most common types of fixed-barrier crossings are Z-crossings and bedstead barrier crossings.

The Z-crossing is designed to turn pedestrians toward the direction of approaching LRVs before they cross each track, forcing them to take note of potential danger. They are typically used at mid-block (away from intersections) pedestrian-only crossings. Bedstead barrier crossings are similar to Z-crossings, but their design is more compact so that they can be used in tight urban spaces.

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 19
Pedestrian Z-Crossing configuration used in combination with a pedestrian signal (urban environment, median operation) San Francisco (California)

Pedestrian swing gate installation (suburban environment, separate r-o-w) San Jose (California)

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 22
Pedestrian swing gate installation (urban environment, separate r-o-w) Los Angeles (California)

The barriers are placed in an offset, maze-like manner that requires pedestrians moving across the LRT tracks to turn toward the direction of approaching LRVs before they cross each track. Both Z-crossings and bedstead barrier crossings can also be used in combination with other devices such as signals or automatic gates. Figure 19 depicts a Z-crossing in San Francisco while Fig. 20 shows a bedstead barrier crossing in Bordeaux, both used in combination with pedestrian signals and supplemental warning plaques.

Moveable barriers are used to restrict pedestrian movements as they are about to enter into the dynamic envelope of the LRV. The barriers can be automatically activated and deactivated by an LRV as it approaches and departs the crossing, or they can be operated manually by the pedestrian. The two most common types of moveable barriers at LRV crossings are the swing gate and the pedestrian automatic gate.

A swing gate is a manual device that requires a pedestrian to pull the gate in order to enter the crossing and to push the gate to exit the protected track area. Operating the gate alerts pedestrians to the presence of the LRT crossing, forces them to pause, and prevents them from running freely across the LRT tracks. Swing gates do not lock when closed and are designed to return to the closed position by gravity after passage of the pedestrian.

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 23
Pedestrian automatic gate with secondary arm (suburban environment, separate r-o-w) Dallas (Texas)

Light Rail Transit in the US and Abroad, Examination of History and Innovations. Figure 24
Pedestrian automatic gate with push gate as escape path (urban environment, separate r-o-w) Los Angeles (California)

Swing gates are often used in conjunction with channelization barriers, LRV-activated internally illuminated signs, flashing light signals, and audible warning devices, as shown in Figs. 21 (San Jose) and 22 (Los Angeles), in order to achieve a higher level of positive pedestrian control at the crossing.

Pedestrian automatic gates are configured and operate much the same as vehicular gates, except that the arms are shorter and may include one or three red lights at the center or the tip that flash when the gate is activated. When used at pedestrian-rail at-grade crossings, the gate arm is located approximately 3 feet above the pathway when in the horizontal position.

At those locations where there is a concern about pedestrians ducking under the arm when the gate is closed, a secondary arm may be installed to hang below the primary arm, as shown in Fig. 23 for the Dallas LRT system. Pedestrian automatic gates are used to physically discourage pedestrians from crossing the LRT tracks when an LRV approaches the crossing, particularly at locations with inadequate stopping sight distance.

Because pedestrians may approach the crossing from both ways, the preferred method for pedestrian automatic gate installation is to provide them at both sides of the crossings (in all four quadrants when installed at motor vehicle and pedestrian grade crossings). Establishing clearly marked pedestrian safety zones and escape paths minimizes the possibility of trapping pedestrians in the LRT right-of-way when

pedestrian automatic gates are used at both ends of the crossing. An emergency exit swing gate can be used for this purpose, designated for use only as an escape route for a pedestrian that may remain between the track and a lowered automatic pedestrian gate. Figure 24 presents an example of the placement of emergency exit swing gates at the Los Angeles LRT system.

Future Directions

The previous sections have shown that although accidents between pedestrians and LRVs are the least common type of LRT accident, they are by far the most severe. A means of addressing and minimizing this type of accidents is by installing devices that convey to pedestrians the higher level of risk associated with violating a closed LRV crossing. The types of devices used to control pedestrian travel across the LRT tracks and warn them about the presence of an approaching LRV include regulatory and warning devices (both passive and active), delineation markings, and positive control devices. These pedestrian control devices are typically implemented in combination in order to achieve a higher level of pedestrian control at the LRT crossing.

Commingled operation Transit trains and freight trains are separated by headway intervals measured in minutes in an operating schedule.

Light rail transit Also called streetcar, tramway, or trolley, is a system with passenger rail cars operating singly or in short, usually two-car, trains on fixed rails in right-of-way that is not separated from other traffic for much of the way.

Shared corridor Transit and freight operators share a transportation corridor, but tracks are separated by at least 25 ft and no more than 200 ft.

Shared right-of-way The transit vehicles run on separate tracks, but track centers are less than 25 ft, that is, separation between the centerline of the freight track and the centerline of the passenger track is less than 25 ft.

Shared track Heavy or LRT vehicles operate on the same tracks used by freight trains.

Temporal separation Both transit and freight trains utilize the same track but are separated by time windows.

Definition of the Subject

Interest in light rail transit (LRT), as a viable urban transportation system, has been growing worldwide and new LRT systems are appearing in urban areas of many countries. One advantage of LRT is its ability to use existing railroad infrastructure to reduce construction cost and environmental impact. The majority of LRT systems in the USA share right-of-way, or utilize the same tracks but temporally separated from the freight railroads, while commingled or simultaneous operation has been common practice for many countries in Asia and Europe. With the success of LRT applications in recent decades, service providers are looking for more space and infrastructure for expansion. Interest in applying overseas commingled experience in the USA has been growing.

Current Federal Railroad Administration (FRA) policy, dominated by safety concerns, does not allow commingling of LRT and freight rail operations within the same time period. The general practice is that light rail agencies own or control the track system, operate transit service as the host, and lease or permit freight operations in off-peak periods. The majority of the freight rail is local deliveries to businesses involving relatively short, slow-moving trains.

Most of the new light rail services operate through central cities on city streets, but new light rail services tend to be extended into the suburbs on private right-of-way, with longer station spacing. Though the commingled operation between LRT and freight railroad is a practice adopted in Europe, it is currently not permitted in the USA. However, with the technical innovations in rolling stock and control systems, more LRT service providers are looking at the potential applicability of European experience in the USA, and the feasibility of commingled operation between LRT and freight railroad is increasingly being discussed.

According to recent studies [1–3], FRA defined three types of shared-use transit and freight operations, which are shared track, shared right-of-way (ROW), and shared corridor.

Shared Track: Heavy or LRT vehicles operate on the same tracks used by freight trains. FRA regulations govern this type of operation, in which time separation, that is, no simultaneous operation of freight trains and LRVs, is required in most cases.

Commingled Operations (Mixed Operation): Transit trains and freight trains are separated by headway intervals measured in minutes in an operating schedule. Though this approach occurs in Europe and Japan for all sorts of transit operations, it is only approved for commuter services governed by rigid FRA rules in the USA. Joint operation between LRT and freight railroad operation is not allowed [1].

Temporally Separated Operations (Time-Separated Operation): Both transit and freight trains utilize the same track but are separated by time windows. In North America, the common practice is to operate transit during the day and freight at night, generally in the early morning hours [1].

Shared Right-of-Way (ROW): In this case, the transit vehicles run on separate tracks, but track centers are less than 25 ft, that is, separation between the centerline of the freight track and the centerline of the passenger track is less than 25 ft. FRA requires railway maintenance workers to observe specific safety precautions when multiple main tracks are adjacent.

Shared Corridor: Transit and freight operators share a transportation corridor, but tracks are separated by at least 25 ft and no more than 200 ft. FRA believes that intrusion by derailed freight or transit cars onto a parallel railroad track is unlikely beyond 200 ft, so does not consider separations of more than 200 ft to be shared corridor for purposes of safety regulation.

Commingled operation, for the purpose of this entry, is defined as "simultaneous train operation on shared track by railroad trains and by light rail transit vehicles that are not fully FRA compliant." Shared right-of-way, similar to FRA's definition "adjacent tracks," is "the arrangement that the track center spacing between the freight track and adjacent LRT track is less than 25 ft." Shared corridor is "the arrangement that the track center spacing between the freight track and LRT track is more than 25 ft but less than 200 ft."

Seeking a better understanding of the current interaction practices between rail transit and freight railroads, the first three sections of this entry presents the historical background and the general landscape of shared-use practices in the USA and overseas, which are largely based on a survey of transit and freight railroad interaction in North America and extensive research and communication with their counterparts overseas. The fourth and fifth sections of this entry discuss potential demands and challenges faced by transit service providers and freight railroads when and if commingled operation is permitted in the USA. Potential solutions and future directions of research are included in the last two sections.

Introduction

Congestion on highways and urban streets has stimulated renewed interest in rail transit in a large number of US cities. Data compiled by the American Public Transportation Association (APTA) reveal that, over the past three decades, total passenger-miles carried by US public transit almost doubled, from 30 billion in 1997 to 53 billion in 2007 [4]. Among the modes of rail transit, the number of unlinked passenger trips by Light Rail Transit (LRT) quadrupled, from 103 million in 1977 to 419 million in 2007, as shown in Fig. 1. The explosive growth of LRT usage has largely been propelled by the renaissance of LRT in the USA after the long decline of streetcar and interurban systems between 1920 and 1960.

An attractive feature of LRT is that it can use some of the existing real estate of the general railroad system, which significantly reduces the cost of construction and environmental impacts by eliminating the need to build a new rail corridor. However, physical incompatibility, disparate operating practices, and safety regulations have led to separating the two operations temporally. To better understand the interaction between light rail transit and freight railroad, this entry highlights the difference between LRT and freight railroad operations and critical issues in shared use of railroad infrastructure. There are major structural differences between the Federal Railroad Administration

Light Rail Transit, Shared Infrastructural Issues. Figure 1 Historical Growth of LRT Usages Source: Based on Data from APTA, 2009

(FRA)-compliant cars and light rail vehicles (LRV), therefore FRA requires that, to minimize or eliminate the risk of collision between the two types of equipment, complete physical or, at least, temporal separation of their systems must be established.

A few LRT service providers, reaping the benefit of newly developed LRT, and at the same time facing the capacity constraints for more LRT services, are willing to challenge the temporal separation rules. The idea of commingled operation may not be totally irresponsible thinking, given the fact that a number of commingled operations do exist in Europe and Asia [5].

Historical Background

A brief review of historical development of LRT and shared-use issues may help to understand the origins of the conflicts and expedite the pace to derive solutions. Congestion along highways and urban streets in a large number of American cities has stimulated renewed interest in guideway transit, especially light rail transit (LRT). The interest in commingling freight and passenger trains intensifies as potential LRT projects appear on the drawing board or join the existing transit systems in service. The inevitable interaction between railroad and transit stirs up great concern about the safety of these services when they share common track, right-of-way, or corridors. It also raises issues of track capacity, and multiple institutional issues relating to ownership of the right-of-way, control, access, liability, and similar matters.

The modern-day light rail transit (LRT) can easily trace its origin back to horse-drawn wagons or omnibuses in the nineteenth century. Its closest relatives or direct ancestors are "streetcar," "tram," "cable car," or "trolley," some of which are still operating today. The terms are often used interchangeably, even by professional transportation planners and engineers. In the USA, ridership data and operating statistics of streetcars, trams, and trolleys have all been aggregated under the LRT category and can be traced back to 1902 [6]. Figure 2 demonstrates the intensity of streetcar operation in Newark New Jersey during the early twentieth century, and is representative of the USA during that period.

There are a large number of books, papers, and web sites documenting the historical demise of the guideway transit industry in the USA and around the world [7–9]. Some of them have developed theories and hypotheses on the reasons underlying the dramatic mid-century drop in transit usage and others have presented vivid images, such as the one documented in Fig. 3. Limited by the length, this entry has no choice but to leave the colorful stories, sometimes romantic connotations, of streetcars or trams to focus on the modern-day LRT, which is the key stakeholder in the shared use of railroad infrastructure.

Along with increasing gasoline prices and roadway congestion in the 1970s, there came increasing doubt that a single mode or technology, even as flexible and comfortable as the automobile, could effectively serve the broad range of activity patterns and travel demand in large metropolitan areas. Facing the dilemma of extinction or renewal and growth, the lonely survivors of a half-dozen streetcar or tram systems in America, as shown in Fig. 4, became the focus of the transportation professionals. The first national conference on light rail transit, organized by the Transportation Research Board, National Research Council, was held in Philadelphia in 1975, which may serve as a symbol that LRT development in America was at that time opening a new page.

Joining the renaissance of LRT development, San Diego, CA; Buffalo, NY; Portland, OR; San Jose, CA;

and Sacramento, CA established new LRT services in the 1980s. Of these, San Diego LRT initiated shared use of railroad track with freight operations. Their negotiations with freight railroad and navigation of federal regulations will be highlighted in the following section.

According to the 2009 Public Transportation Fact Book published by APTA, the latest data available, by 2007 there were 33 LRT operations, with 1,810 vehicles available for peak service in the USA. The total LRT track miles reached 1,517 miles, including 144.1 miles in

Light Rail Transit, Shared Infrastructural Issues. Figure 4
The Timeline of Major Streetcar Systems in the North America

construction and design and 561.7 mile in future planning as of September 1, 2008. The total number of unlinked passenger trips by LRT had reached 419 million, still a far cry from 13 billion during its heyday in the 1920s, but a fourfold growth from 103 million, the darkest days for LRT in 1977.

As defined by the Transportation Research Board and adapted by the US Department of Transportation [10], modern-day light rail transit is "a metropolitan electric railway system characterized by its ability to operate single cars or short trains along exclusive rights-of-way at ground level, on aerial structures, in subways, or occasionally, in streets and to board and discharge passengers at track or car floor level." Operating along the old tram or streetcar alignment or built along brand new corridors, the modern-day LRT has made great strides in rolling stock technology, which leads to higher efficiency, quick operating responsiveness, and high speed, especially when separate rights-of-way are used.

If the definition by TRB and USDOT has emphasized the operating environment and characteristics of LRT, the definition by America Public Transportation Association (APTA) has focused on the capacity. It states that light rail transit is "an electric railway with a 'light volume' traffic capacity compared to heavy rail. Light rail may use shared or exclusive rights-of-way, high or low platform loading and multi-car trains or single cars."

Joint operation of passenger and freight railroad services is not a revolutionary concept. It has a long tradition in the USA over the last century and is widely practiced in Europe, Asia, and other parts of world [11–13]. However, current Federal Railroad Administration (FRA) policy dictates that freight and LRT trains using the same track must be separated by time of day, primarily because light rail vehicles (LRVs) do not comply with FRA crashworthiness regulations. On the other hand, applications of commingled operations of freight and LRT have been growing overseas, notably in Europe and Asia, where light rail services share track with conventional freight and/or passenger rail services without time-of-day separation.

The commingled operation of freight and LRT, given the growing interest in providing similar services in the USA, has caught the attention of transit operators, government agencies, and the research community. This entry highlights the concerted effort by the FRA, Federal Transit Administration (FTA), and Federal Highway Administration (FHWA), to explore the innovation concept and feasibility of integrated rail operations of short-line or lightly used freight railroads and LRT.

On July 10, 2000, FRA and FTA jointly issued the statement entitled "Joint Statement of Agency Policy Concerning Shared Use of the General Railroad System by Conventional Railroads and Light Rail Transit Systems" (Joint Policy Statement) [14]. The Joint Policy Statement explains how the two agencies will coordinate their safety authority with regard to the sharing of track by rail transit and conventional railroads. On the same date, FRA issued its statement entitled "Statement of Agency Policy Concerning Jurisdiction over the Safety of Railroad Passenger Operations and Waivers Related to Shared Use of the Tracks of the General Railroad System by Light Rail and Conventional Equipment" (Policy Statement). The Policy Statement gives policy guidance and explains the legal basis for safety jurisdiction and agency policy on exercising the same in a shared-use context.

The Joint Policy Statement is general and procedural in nature, while FRA's Policy Statement contains more substantive guidance and practical details. According to FRA, transit operations that will share use of the general railroad system trackage must either comply with the FRA's safety rules or seek a waiver. FRA will be more likely to waive many of its rules where "temporal separation" is in effect and the petitioner demonstrates that its system safety program and state safety oversight program address relevant safety issues. If the transit and conventional railroads operate simultaneously on shared tracks, the petitioners will face a steep burden of demonstrating that extraordinary safety measures are taken to adequately minimize the likelihood of a collision between conventional and light rail equipment. Where a rail transit line shares only a common right-of-way with a general system railroad line, FRA does not consider that situation to involve shared use, and a waiver is not necessary.

The primary reason that collision safety is a major issue is that the structural strength of typical light rail equipment is well below the requirements for rail passenger vehicles, as specified in 49CFR Part 238, reference to the latest edition of FRA safety regulations in

CFR Parts 200–299. A manuscript by a FRA Staff [15] provides an overview of the policy statement with respect to shared track and limited connections. A few tables outlining the likely treatments of various subject rules are given and examples include track, structure, signaling; motive power and equipment; and operating practices. These examples provide helpful guidance for transit operators interested in applying for waivers. A large portion of the entry is devoted to shared rights-of-way and limited connection categories. The author made the following statement on the shared track and commingled operations:

- For joint simultaneous operations on shared track, the petitioner will face a steep burden of demonstrating measures taken to reduce likelihood of collision between light rail and conventional equipment. Fully integrated joint operations, such as the Karlsruhe, Germany system, include advanced train control systems required for all equipment. Accordingly, transit operator will be required to observe the same rules and procedures as the general system, i.e., FRA is less likely to waive rules such as engineer certification for light rail operators.

In another elaboration of the Joint Statement, Sheys and Spear [16] summarized FRA's treatment of shared-use safety issues in petitions filed by Utah Transit Authority (UTA), New Jersey Transit (NJ TRANSIT), and Santa Clara Valley Transportation Authority (VTA). UTA sought a waiver from the injury report requirements, Hours of Service Act record-keeping regulations, and the requirement for flagging a crossing in the event of a grade-crossing activation failure. FRA granted all UTA's requested waivers conditionally, except for part of the Hours of Service Act record-keeping. NJ TRANSIT sought a waiver of several FRA rules related to window glazing and emergency window exits. FRA granted the petitions but required NJ TRANSIT to conduct a public education and awareness campaign to familiarize residents of the area with the new service on the line. VTA's petition related to a 7.6 mile extension, 1.6 miles of which involve temporally separated transit and freight use of a rail corridor, but only extremely infrequently, that is, three or four times per year. This case indicates that FRA is likely to treat shared track/temporal separation cases involving very infrequent usage differently than those involving routine freight usages.

The American Public Transportation Association (APTA) formed a Shared-Use Working Group (SWG) in 1999 when the Federal Railroad Administration and Federal Transit Administration were developing the Joint Policy Statement and Final Rule. The purpose of the SWG was to press for consistent and flexible regulation of transit operations in corridors shared with the general railroad system. The SWG has brought together general managers of transit agencies, federal officials, and technical specialists for a series of energetic, well-attended meetings and forums. The SWG is currently cochaired by John Inglish of the Utah Transit Authority, and Thomas Hickey of Houston Metro.

There were also a few studies addressing the subject of commingled operation of freight and LRT since the late 1990s, among which, three Transit Cooperative Research Program (TCRP) studies, one FRA-sponsored study, and their related publications are most notable and are summarized below.

The Transportation Research Board commissioned a concerted research effort to explore various issues associated with joint operations between light rail transit and freight railroads, driven by the large numbers of urban areas in the USA that were contemplating new or expanded rail transit services, especially where active railroad trackage provides an opportunity for potential cost-effective joint use.

The first TCRP research [13] was conducted and completed before the publication of the FRA/FTA Joint Statement. It reviewed a number of joint operations domestically and overseas and summarized four categories of critical issues related to commingled operations: regulation, operation, infrastructure, and vehicles. The study pointed out that one should be very careful when talking about transferring overseas experiences to the USA. There are a number of different circumstances, such as traffic mix, labor agreements, and safety features that make simple replication of these systems in the USA very difficult. Even the sampling operations in Germany and Japan maybe very different: while in Germany one can find light rail, passenger railroad, and freight railroad sharing track, in Japan these examples are very rare. If it occurs, track sharing is most often by passenger railroads and transit operators. Therefore, all the factors mentioned above vary from case to case and must be studied

independently. The TCRP research also recognized that differences and variations in standards among rail systems in the USA, even in neighboring metropolitan areas, make joint operation even harder to accomplish. The interchange of rolling stock is also very hard to achieve due to all the institutional and technology requirements, even though the use of one another's rolling stock on different commuter lines does occur for various reasons.

In order to recognize the FRA and FTA joint statement of policy concerning shared use, the principal authors of TCRP Report 52 produced another TCRP report [5]. After a brief review and summary of FRA/FTA joint statement and TCRP Report 52, the author proceeded to provide some additional information on Karlsruhe and other track-sharing locations that had occurred since the publication of TCRP Report 52. The detailed descriptions of various locations in Germany are very useful to researchers to identify potential models/aspects for application in North America. The article clearly identified that Karlsruhe may be an ideal model but not for direct application in North America. It also urges others to examine some less intense, simple, and straightforward interactions, such as those at Durren or Zwickau, for more transferable applications in the USA.

The article also emphasized the validity of major issues identified in TCRP Report 52. It included a matrix of interest groups or stakeholders and the intensity of their interest in the shared-use issues. The author provided some key issues and policy suggestions for further research in four large areas: regulation, operation, physical plant and infrastructure, and vehicle. A few key questions raised in this article are directly relevant to the understanding of shared-use issues:

- Is joint use a sound policy worth advancing?
- What risk mitigation measures can be applied to shared track to reduce the risk to tolerable levels?
- Does joint use constitute a hazard to public safety?
- What are the quantifiable risks and liabilities arising from various degrees of joint use?

As an introduction of "shared-use operations" to the general transportation community and a freestanding statement of current conditions, Phraner [17] presented another report at the 8th Joint Conference on LRT in Dallas, which provided a definition and then current applications of joint use. The article also listed motivations and deterrents to shared use.

Another study conducted by the Volpe National Transportation Systems Center [18] for FTA focused on safety and insurance issues. Shared-track operations involve some unique risks, and the liabilities associated with these risks can affect whether such services are offered and, if offered, their operating plans and costs. Insurance is used to mitigate or manage such risks and insurance premiums can be a significant cost item for transit agencies. The authors explored the issues of liability and insurance that arise when operating on track shared between light rail transit and freight railroads. The study included six shared-track operations. The transit agencies that currently operate light rail transit on the same track as freight railroads are: San Diego Trolley, Inc. (SDTI), Utah Transit Authority (UTA), New Jersey Transit (NJ TRANSIT), which has two services, the River Line and Newark City Subway, and the Maryland Transit Administration (MTA).

The most salient risk involved in shared-track operations is that of a collision between a light rail transit vehicle and a freight railroad vehicle. None of the shared-use agreements specifically addresses the possibility of this kind of risk, since it has never occurred. Other risks include one party damaging the other party's property. Track ownership seems to have a significant effect on risk. Part of the reason that freight railroads agree to sell the ownership of track to transit operators is to avoid risk. Some insurance industry officials believe it would be useful to have a study that could quantify the perceived risk of shared operations. However, there has been no published risk assessment performed specifically for the case of shared track between light rail transit and freight railroads until the two recent FRA studies, which will be addressed in the following section.

Freight railroads generally try to minimize their risk for anything related to passenger transit. Based on the six case studies, there are three basic methods for assigning liability: by fault; by financial threshold; and by incident circumstances. By fault is the simplest way to address the issue. However, when the fault for an incident is not clear or if multiple parties are involved, the process of fault determination can be lengthy. Financial thresholds are easier to determine. In many cases cutoff points assign liability. Liability assignment

by circumstance describes various situations and assigns liability based on who is involved and the type of damage is caused. When liability is assigned by financial threshold or incident circumstances, one party is held harmless irrespective of fault. In these cases, there is an implicit lack of incentive for safe behavior.

According to the study, there is no instance where separate liability insurance for the shared-track operations exists because the safety rules and procedures are viewed as effective in mitigating possible risks. A table included in the manuscript gives an overview of the various insurance levels and premiums for each of the case studies. Insurance level varies by agency from $35 million to $250 million and annual premiums ranged from $150,000 to $4.2 million.

The primary objective of another FRA study [19] was to explore the feasibility of concurrent operations of compliant and noncompliant vehicles on the same track, concentrating on identifying and evaluating risk mitigation measures that would meet FRA's requirement of providing "equivalent safety." The study was deliberately constrained to existing noncompliant vehicle types proposed for LRT services in North America, and sharing track with low-density local freight service to best represent the current interest.

The study summarized principal vehicle characteristics and physical plant for five potential shared-track operations, which include: Baltimore LRT in Maryland, SPRINTER DMU from Oceanside to Escondido in California, the River Line in southern New Jersey, San Diego Trolley, and TRAX light rail in Salt Lake City, Utah. The areas of noncompliance, issues related to shared use of LRT and freight railroad, such as railroad operating and maintenance practices, equipment, and operating environment, are discussed.

After furnishing a table summarizing the effects of noncompliance on accident likelihood and severity, the report provided a risk analysis of a representative noncompliant passenger rail operation with concurrent local rail freight service. The primary area of concern with commingled operation is the number and severity of collisions between noncompliant vehicles and conventional freight cars and locomotives. The risk analysis results showed that the incremental risk from shared operation could be mitigated by practical risk mitigation measures, provided that freight operations are confined to a small number of trips during off-peak hours. Mitigation measures include adding a second track to a single-track system, and applying one of several alternative train control systems to reduce the risk of a collision.

A recent draft implementation strategy developed by Tereschuck [20] outlines the core operational requirements for retention of an equivalent level of safety for commingled operation of freight and LRT services. Based on previous TCRP research and Federal fact-finding mission trips to Europe, the author highlighted five essential operating characteristics consistent with the European approach to commingled operations. Corresponding to each characteristic, the manuscript also presented possible actions for pilot application:

- Single authority/ownership of rail corridor/dispatching control
- Uniform/single rule book authority
- Single communication network
- Consistent training/certification process – single authority control
- Application of advanced technology – provide positive train stop or automatic train control capability

A recent study [2], sponsored by FRA, has reviewed the technical feasibility of concurrent shared-track operations in detail focusing on the 1999 FRA/FTA Shared Track Policy Statement, which identifies six factors to be considered in evaluating the operational safety of light rail transit systems that would share track with conventional railroad equipment. The research team pointed out that five of these factors are primarily operational in nature requiring appropriate organization and training but no investment in technology. The final factor, fail-safe train separation and collision prevention, revolves around the deployment of appropriate technology to prevent collisions between trains. Relative to the primary technical consideration of providing fail-safe train separation, the team has identified a number of train control systems that ensure trains sharing track do not collide. All of the systems override the vehicle operator in the event of a signal violation that could result in a collision with another train.

Independent of the federal shared-track policy, the research team identified and evaluated the four most salient risks of concurrent shared-track operations.

The study team found that risk assessment is a valuable tool that can contribute to assuring the safety of commingled shared-track operations. Risk assessment is any structured process of identifying the hazards present in an operation, evaluating the level of risk associated with the hazard, assessing the acceptability of the risk, and determining whether or not risk mitigation will be required. Risk assessment may be applied at all stages in the development and operation of a passenger rail system, but the primary purpose for a shared-track operation is to support the customary safety assurance process for a new shared track operation through planning design and implementation stages.

In addition, the FRA study has also conducted a market assessment to support federal investment in mechanisms and methods that facilitate shared-track operations. The market assessment indicates substantial national applicability and considerable industry interest in concurrent shared-track operations where light transit cars share track with conventional railroad trains. In the context of national applicability, a nationwide review of the 88 urban areas with populations greater than 500,000 inhabitants identified 165 corridors in 65 cities with potential for development as shared track freight/transit rail services. Relative to industry interest, a brief scan identified 15 North American corridors where shared track operations are in current operation, design/construction, or active planning.

The most recent TCRP Report 130 [3], produced under the TCRP A-27 project, has focused on the present and evolving state of the art in the shared-use environment, specifically examining train control technology, operating rules and procedures, communications systems, vehicles, shared-use operations, and governance and business models of existing and planned systems.

The research team took a comprehensive view of "Command and Control" as including the variety of train control and communication systems, operational rules and procedures that are particularly suitable or adaptable to the shared-track environment. The emphasis was on those features that compensate for vehicle structural deficiencies by minimizing the risk of a collision in such an integrated system.

Building on knowledge gained via previous studies, the TCRP project presented the characteristics of freight railroads, suggested business models for future implementation, and included a business case and practical guide for transit agencies or other stake holders to be involved in the shared-use area. To carry the TCRP A-27 to a new height, the study team developed a hypothetical case study and recommended a demonstration program to explore the critical issues and feasibility of sharing track between FRA noncompliant LRT vehicles with lightly used freight railroad operations.

There are various studies, trip reports, and research summaries that document overseas practices in the areas of commingled operations of freight and LRT. The literature presented here may overlap on some cases in Europe but the emphasis and time frame may vary.

Geissenheimer [21] published a manuscript that recognized the opportunities to operate efficient rail service on sparsely used lines using a new generation of self-propelled diesel multiple unit cars (DMUs) or dual-power electric light rail vehicles (LRVs) combined with changes in operation and organization. The focus of this article related to vehicle technologies and their applications, but also provided some pioneer study of shared use cases in Duren and Karlsruhe, Germany; Amsterdam, Holland; and briefly mentioned shared use in Japan and Korea.

Another early introduction to overseas shared-use practices was included in a short article in the Journal of Transportation Engineering [22]. This article highlighted two basic strategies to develop a local LRT or streetcar network into a regional system at relatively low cost. The first strategy is to take over a railroad line, where most or all prior freight service has been or can be abandoned. Examples mentioned in the USA include the Riverside Line in Boston and LRT service between downtown San Diego and the Mexican border. The second strategy is to implement a shared track agreement that provides LRT access to the railroad with freight services. As documented in this manuscript, in contrast to the requirement by the US government regulations, for LRV to meet high buffing strength standards to protect against damage in the event of collision, there is no special buffing strength requirement in Germany. The rationale is that LRV braking rates, being superior to those of main line trains, obviate the need for buffing strength.

The author presented a detailed network and vehicle arrangements of Germany's Karlsruhe system to demonstrate the principles of shared-use applications. A few other applications were also mentioned in the article: Kassel, Saarbrucken, and Zwickau in Germany and other cities in France and Switzerland.

Another detailed study of shared track operations in Karlsruhe is presented in the FTA/FRA fact-finding trip report [23]. In March 2000, a delegation of US transit operators, equipment manufacturers, and consultants led by FTA/FRA went to Karlsruhe to examine shared track operations. After describing the nature and importance of rail transportation in Germany, the trip report documented how shared track operation was achieved in Karlsruhe. Summarizing general observations and specific case studies during the trip, the delegation highlighted the following factors that contributed to the success of shared track operation in Karlsruhe

1. A government-owned national railway system provides accessibility to all rail tracks.
2. Information, communications, and active train control systems and equipment adaptable to mixed usage are employed.
3. Government also requires the labor force to obtain licensing certification to operate the different types of trains running in Karlsruhe, including trains for freight, intercity passengers, regional passengers, and local trams.
4. Institutional factors, such as common operating rules, dual dispatching facilities, and uniform safety regulations, ensure the seamless integration of both light rail and conventional rail operations.

As a member of the delegation of the fact-finding trip organized by FTA/FRA in 2000, Phraner also visited additional cities, such as Saarbrucken, Duren, and Koln. A supplemental report [24] was compiled to provide an independent supplemental study of those systems visited. Recognizing Karlsruhe as an instructive case study but not a readily transferable model to North America, the author defined Karlsruhe as representing the most advanced example of shared track operations. The Karlsruhe case study provided selective lessons and precedents in institutional and regulatory innovations that encourage shared track arrangements. Karlsruhe practice demonstrated operating practice extremes by dispatching tram and mixed LRT train traffic through a peak volume point and confirmed that the German train control technology and control center operated safely.

Another important issue in the Karlsruhe practice is the exemplification of strong political leadership and commitment, necessary to accomplish a shared-use project. Besides abundant field visit photographs of each location, this report also included detailed network maps, schedule, and operating arrangements for Saarbrucken, Duren, and Kohn case studies. One of the important contributions of this report was to identify the potential issues to be encountered in the USA when/if a particular model is to be transferred. In addition, the report also devoted an entire chapter to light-rail-derived DMU rail cars and discussed their importance to shared track in North America.

Similar to previous fact-finding trip reports, the TCRP Research Result Digest Number 47 [23] documented a number of case studies of shared track operations in Germany (Kohn, Durren, Kassel, Karlsruhe, Saarbrucken, Rhine/Ruhr-Dortmund, and Gelsenkirchen), France (Strasbourg), and Luxembourg City. Different from the previous fact-finding trip report is that this digest is organized by functional areas, such as design, technology, and track-sharing relationship to economic and urban development. Each area is demonstrated via specific examples of various cases in Europe. Its Appendix C provided a summary table of German cities with track sharing operations, which may be useful to identify the unique characteristics and similarities of various shared track operations.

Another recent description of shared track operations appeared in the Tramways & Urban Transit Magazine [25]. In this article, the author described a visit to a German city transformed since the end of communist era. Nordhausen, a former part of East Germany, has access to two meter-gauge tramlines. One runs to an informal transfer center with two railway stations and serves a large number of urban, suburban, and interurban bus routes. The Deutsche Bahn Station, a typical busy urban facility, has intercity and regional trains arriving and departing at frequent intervals. The Bahnhof Nord, the terminus of a privately operated but highly subsidized meter-gauge railway system, runs through rural areas and forests and is used

primarily for passenger traffic, with diesel railcars and steam-hauled trains attracting commuters, schoolchildren, and tourists.

Similar to most US cities with growing suburban and rising automobile ownership, Nordhausen wanted to improve transit service and discourage motor traffic from clogging its streets. Following the examples of Karlsruhe, it was thought that a tram-train operation providing through service might substantially reduce the number of cars entering the city. Encouraged by the no-transfer service and low-cost solutions, Nordhausen simply built a track connection between the two systems and a hybrid vehicle to run on busy streets under typical 600 V tramway overhead and self-propelled on traditional railway tracks. Service over the connection began in April 2002 and an extended service of 12 km beyond the privately operated station was inaugurated in May 2004. As observed by the author during his visit in 2005, the shared-use operation in Nordhausen is "very elegant." Using sophisticated layover procedures, the shared track operation provides sufficient service for commuters and makes significant contributions to the local economy.

Current Operating Scenarios in the USA

It is important to have a general understanding of the current LRT operations in order to explore the issues of shared use of infrastructure with freight railroads in the USA. A brief presentation of a national survey of shared use between LRT and freight railroads in North America is included below. The survey results are categorized into four groups: physical characteristics, operating privileges, insurance liability, and regulation.

The difference between propulsion power, capacity, and operating characteristics determined that LRT operations have different issues from commuter rail services, even though they may share certain legal, administrative, and organization issues. According to a recent survey [1], among the 34 LRT operations in North America, about a quarter do not have any interaction with freight railroad and the rest all interact with freight railroad to some extent, as shown in Fig. 5. The majority of the LRTs surveyed, 61%, interact exclusively with local freight; SEPTA light rail interacts exclusively with mainline freight and another light

Light Rail Transit, Shared Infrastructural Issues. Figure 5 Types of Interaction between LRT and Freight Railroad

rail transit. It is interesting to note that, in the case of Edmonton LRT, the interaction with the adjacent freight main line has diminished due to changes in freight operations since LRT was built in 1978. At that time, the LRT route was located between main line tracks. Now the alignment is a little used freight spur.

Platform access level is an important element in the interaction between LRT and freight railroad. The Americans with Disabilities Act (ADA, 1990) requires that transit systems provide level access for passengers. Unlike a commuter railroad, whose platform access level can be categorized as low-level platform and high-level platform, LRT platform access level may be better described as "low-floor" versus "high-floor" configuration. In case of low-floor access, the LRT vehicle floor is flush with station platforms that are 8–14 in. above the track, depending on the system, so wheelchairs or strollers can roll on to the vehicle directly. Low-floor cars, which have been used in Europe for more than a decade, were only first introduced to USA in 1997 on Tri-Met MAX in Portland, OR.

Most early low-floor designs were intended for city streetcar or tramway applications and have neither the top speeds nor the ride quality suitable for US and Canadian light rail operations. However, many European LRTs have extensive on-street operation and recent new vehicle procurements have been predominantly for the low-floor type [26]. In the most recent decade, partial low-floor LRVs capable of 55–65 mph top speeds have been delivered to several US cities. These vehicles are capable of providing the speeds and

levels of comfort needed to effectively serve regional LRT lines of 10–20 miles in length.

When high-floor LRT vehicles are used, the floor is higher than the station platform so wheel chairs have to be aided by a lift to roll onto the vehicle. There are often mini platforms situated at the end of the platform so that they can be operated by the train driver when required, which is the case in Sacramento, Dallas, Baltimore, Denver, Salt Lake City. San Diego has elevators mounted on the car itself. High platforms are used exclusively in a number of systems including Los Angeles, St. Louis, Edmonton and Calgary. They are also used in combination with low level loading platforms. Examples include Buffalo, Pittsburgh, and San Francisco. A precise demonstration of both high- and low-floor LRV may be observed in Tri-Met's MAX in Portland, OR. The agency practice coupling one high floor with another low-floor vehicle, this ensures adequate access for wheel chair users at all times and all locations.

As documented in the study [1], the degree of shared operation in light rail transit varies. Five systems, depicted in Fig. 6, share track and are temporally separated from freight operations. They are MTA LRT in Los Angeles, TRAX in Salt Lake City, the LRT system in Baltimore, San Diego Trolley, and Newark Subway in New Jersey. Light rail services usually operate during the day, with freight operations from midnight until the early morning hours. Since that survey was conducted in 2003, a new kid on the block, South Jersey Riverline LRT, has joined the group using the temporally separation arrangement. Six light rail transit systems share right-of-way with freight, with each mode on separate tracks. These include New Orleans Streetcar; SEPTA light rail transit, Denver LRT, Portland MAX, Sacramento LRT and Hudson Bergen LRT. Only the Metro Blue, Green and Red LRT lines, in MTA of Los Angeles, and Edmonton Transit have some shared facilities with freight, but no joint usage.

Light Rail Transit, Shared Infrastructural Issues. Figure 6 Types of Freight Railroad Interacting with LRT

In contrast to the mixed ownership of tracks used for commuter rail operations, the ownership for LRT tracks is distinctly defined. According to the same survey [1], about 40% of the shared tracks are owned by freight railroad and 60% by the transit agencies. In general, LRT either uses tracks abandoned by a freight railroad, or the transit agency has acquired the right-of-way, being abandoned, to preserve transit corridors.

Moreover, most of the light rail transits are dispatched by transit agencies themselves, such as Newark Subway, NJ River Line, Edmonton Light Rail Transit, San Diego Trolley, SEPTA LRT, Baltimore light rail transit, and Metro Blue, Green, Red lines in Los Angeles. Two systems are dispatched by third parties, which include TRAX in Salt Lake City and Hudson Bergen LRT in New Jersey.

When compared to the commuter rail systems that have different dispatching protocols during peak and off-peak period, the majority of the LRT systems implement the same dispatching priority timetable during their operating period, which is largely caused by the temporal separation.

None of the light rail transits surveyed has any incentive plan for better coordination between freight and transit operations. The obvious reason is that light rail transit operators are less affected by freight operation, except during the time window that is allocated.

One of the questions included in the survey asked what measures are provided to separate transit and freight operations. The results indicate that the majority of LRT systems do not have any physical barriers to separate LRT and freight operation when they are in the close proximity of each other. Among the ten valid answers, seven do not have any separation measures between transit and freight, two uses fences, and one uses both fencing and intrusion detection. The last example was dictated by the freight railroad due to liability concerns.

The survey results revealed that generally not many changes were made to the transportation system to accommodate passenger operation for LRT. Most changes were just a complete service time separation schedule. For example, Edmonton Light Rail Transit, where the LRT tracks were originally in the center of the right-of-way with mainline tracks on both sides, gave modification details to accommodate LRT operation: "temporary relocation of CN track during construction of a shared LRT/CN bridge. Also CN grade crossing gates were connected to LRT signals system to allow shared use of the gates. They extended the crossing 'gate call-on' provided on CN line and tied it into the LRT crossing 'call on' signal to allow gates called on by LRT to stay down if CN train was approaching. There was also a need for the modification of CN's DC signal system to ensure that there would not be interference caused by LRT DC traction power return. A signalized diamond crossing was installed on CN track to enable LRT line to cross into their yard that was located across the CN westbound track. All of the above were paid for by the City of Edmonton." Since the construction of the LRT the main line freight service has largely been relocated away from the shared right-of-way.

The settlement of insurance and liability issues between the light rail transits and the freight railroads is similar to that of commuter systems. The size of LRT operation and the strict separation of operations defined the insurance premium, liability, and deductible, which are generally smaller than for commuter rail services. For example, the insurance and liability issues for San Diego Trolley were handled through agreement with Metropolitan Transportation Development Board (MTDB) that both own the freight railroad and San Diego Trolley. In the case of the Baltimore LRT, the State MTA holds CSX harmless. The insurance requirement for Edmonton Light Rail Transit is as follows: $5 million liability insurance covering persons using LRT and CN passenger service; $1 million insurance covers liability to cover third parties arising from utilization by the City of the premises and all premiums are paid by City of Edmonton. City waives its rights against CN for damages arising from occupation/use of the leased premises, except if caused by the negligence of CN.

No accidents were recorded as a result of freight and LRT interaction in the survey [1]. This may reflect the safety precaution of the separated operation. But at the same time, we also have to admit that LRT systems have only been in operation for a relatively short period. The oldest among the several "new age" LRT operations in the USA is the San Diego Trolley, which is only 29 years old. Compared with the century old commuter rail operations, the total accident number is low or nonexistent.

Different from the commuter rail operation, most LRT service providers or transit agencies have purchased and now own the railroad lines. Then public transit entities grant trackage rights to the contract freight operators to access the shared-use tracks. For example, Utah Transit Authority (UTA) bought the railroad track from Salt Lake City to Sandy and beyond from Union Pacific and contracted a short line to provide the residual local freight switching service on the LRT line. Similarly, New Jersey Transit purchased the alignment from Conrail for the Riverline LRT in South New Jersey. Conrail has a permanent operating easement, which provides them trackage rights to use the River LINE per the terms of the sale and operating agreements. Many transit entities are in the process of acquiring the shared-use asset; some properties still inherited the historical arrangements. For example, Edmonton Light Rail Transit and Newark Subway get the corridor access through property lease; SEPTA light rail gets their corridor access through a highway crossing agreement between State and railroad, and San Diego Trolley, Inc. via a contract through MTDB, of which SDTI is a wholly owned subsidiary.

Demand for Commingled Operation

While North America pioneered commingled operation in the early twentieth century, the newest and most innovative forms of joint use are found overseas. Transit professionals found that, in terms of commingled operation between LRT and freight railroad, the combination of US engineering and operations best practices is behind international trends. A few LRT service providers argue that commingled operation is feasible, if certain measures are taken to mitigate risks to tolerable levels.

LRT is a relatively inexpensive transit mode to build, compared with urban highway and heavy rail. Yet, LRT is effective in attracting automobile users from congested highways. For example, Baltimore's LRT was

built in 1992, at the cost of $360 million, for the initial 22.5 miles. In year 2000 dollars, that's approximately $422 million, or $19 million per mile. The cost includes right-of-way purchase, line construction, stations, vehicle procurement, maintenance and storage facilities, etc. According to APTA, Baltimore's LRT carries about 25,600 passenger trips per weekday, which is about 2,500 trips in the highest peak hour, or about 2,400 trips in the peak direction, equivalent to almost two freeway lanes. The LRT system has been planned to accommodate future growth with three-car trains, and with a maximum 2-min headways assumed, the system could theoretically accommodate about 23,000 persons per hour, the equivalent of about 20 freeway lanes [27].

LRTs also have the advantages of lower operating cost. For example, the operating cost of LRT services in Boston, which carries the heaviest LRT ridership in the USA, is significantly less than that of bus services. According to FTA's National Transit Database [28], the MBTA's LRT system carried passengers at an average cost of $1.25 per trip, and $0.51 per passenger mile, compared with MBTA average bus costs of $2.04 per trip and 0.71 per passenger mile.

LRT is the USA's big winner in terms of ridership growth among the major transit modes. Despite the economic recession, Americans took more than 10 billion trips on public transportation in 2009, a 35% increase since 1995 [4]. Among which, LRT ridership remain the most stable, contributed by newly inaugurated systems, in Phoenix, AR and Seattle, WA. In addition, a number of existing LRT systems exhibited large ridership increase, such as 12% in Baltimore, MD; 11% in Oceanside, CA; and 9% in Memphis TN.

LRT operations have been developing at an average rate of nearly one new system per year over the past 3 decades. According to APTA [6], there are 27 modern LRT systems (opened after 1981), and another 7 Vintage Trolley systems in USA. The recent openings of LRT include Portland's MAX Yellow Line, streetcar extensions in Memphis and New Orleans, and New Jersey River Line, which is the first to use non-electrified vehicles. Most extensions in San Diego, San Francisco, San Jose, Sacramento, Denver, Dallas, St. Louis, Philadelphia, Pittsburgh, Baltimore, Hudson-Bergen, and Newark subway are now open. New start-ups in Phoenix, Memphis, Minneapolis, and Charlotte are in operation also.

Most new light rail services operate through central cities on streets from which the bulk of automobile travel has been removed. However, outside of the center cities, the new LRT services typically extend into the suburbs on private right-of-way, with longer station spacing. The general practice is that light rail agencies own or control the track, operate transit service as the host and lease or permit freight operations by a contracting railroad in off-peak periods.

Though most LRT agencies own the right-of-way by purchasing the abandoned or branch rail lines, the demand for commingled operation between LRT and freight railroad might increase when rail transit "new starts" exhaust vacant right-of-way. It is possible that the competition for track space will focus on the active railroad lines, not only abandoned or underused lines.

On the other hand, rail freight is booming as well. For the first time since World War II, some railroads have capacity constraints on certain lines. According to the Association of American Railroads [29], railroads are experiencing a surge in traffic volumes for all commodities, including coal, and, for the first time, intermodal freight is the industry's top revenue source. The US railroads originated more than 330,000 carloads per week in 2008. The transformation from once thought to be stodgy and slow carrier to a good-service, high-speed and modern carrier has made freight railroad an indispensable link in providing "just-in-time" supply chain.

The dilemma faced by both freight railroads and rail transit operators is that rail segments, where passenger service providers require additional capacities, are often bottleneck areas within freight operations. This fact can make it even more difficult to share tracks for both freight and passengers.

Though commingled LRT operation with freight railroad is not active in the USA, it is a common practice in Europe and Japan. The European approach to mixed operations is significantly different from the US approach. European operations maximize utilization of the "track resource" through scheduled, on-time freight and passenger operations [30].

Karlsruhe, Germany is acknowledged to provide the most sophisticated and advanced examples of shared-track practice between railroads and light rail. As documented by the supplement of TCRP 52 [5] Karlsruhe integrated its local streetcar and railroad

service on selected lines. LRVs and commuter trains not only run jointly, but also provide joint service on an integrated timetable, with freight and intercity trains interspersed in the operating schedule. Karlsruhe demonstrates operating practice extremes by dispatching tram and mixed LRT and train traffic through peak volume points. The observation made by TRB [5] disclosed the highest level of operating discipline and performance: 16 trains passing in an hour, nine of which were scheduled northbound in the half-hour interval between 12:30 and 13:00. A northbound freight intercity train is followed 1 min later by a high-speed Intercity Express (ICE) train, 10 min later by a Euro International Express, 4 min later by a light rail vehicle making a station stop, 3 min later by an express freight, 4 min later by freight – all sharing the same track [5].

Japan is another leader in commingled operation between rail transit and freight railroad. Japanese National Railways (JNR) split into six passenger carriers which are separate corporations but are marketed as Japanese Railways (JR) and one freight carrier, JR Freight in 1987. JR Freight and the six JRs operate on the same track and catenary system, using the same railway facilities. Unlike freight services in the USA, freight in Japan is subordinate to passenger services on the national railroad system. Freight operation is consistently the tenant on the passenger railroads. Although JR Freight does not pay track usage fees, it is responsible for the incurred incremental costs of operating freight trains on these tracks. An average of 737 freight trains operates each day throughout the country. Of these, 425 are container trains, while the remainders are trains hauling bulky freight in tankers and hoppers. About 90% of JR Freight's rail freight is transported at night [31]. JR Freight is investing heavily to upgrade its fleet with faster and powerful locomotives; developing new freight wagons for high-speed trains; developing new containers for easier loading and more capacity; and upgrading freight station facilities. An advanced freight system may also contribute to more harmonious operations with the rest of the rail transit modes.

It remains to be seen whether FRA is willing to adopt such practices even though Europe and Japan has proven that commingled operation can provide more line capacity. The RiverLine in Southern New Jersey could be an example of efficient use in the USA. NJ Transit's initial plan, developed with Conrail Shared Assets, called for a "limited mixed-use" operation with parallel running on adjacent freight-only tracks, one freight train per day during off-peak hours, and use of automatic trip-stops and derails. The risk assessment indicated that the safety level would meet FRA's requirement. However, FRA rejected this plan, claiming that freight traffic on the Trenton-Camden corridor is expected to grow, making temporal separation impractical. NJ TRANSIT then replaced the original plan with a more rigid time-separated alternative, day and evening for passenger operations and late night freight operations.

Challenges Faced by the Attempts

Though commingled operation could exhibit advantages, such as lower capital investment for infrastructure, reduced operating cost, cheaper and quicker new starts, etc., challenges are yet to be solved, such as incompatible equipment, signals and communications, and inspection and maintenance practices.

The FRA/FTA "Joint Statement" states, "Although compatible in terms of track gage, these two forms of rail service are incompatible in terms of equipment. A collision between a light rail transit vehicle with passengers aboard and heavy-duty freight or passenger equipment would likely result in catastrophe."

The main problem in the USA is the design of different categories of rail vehicles: FRA requires railroad vehicles have certain crashworthiness or buff strength, while these regulations do not apply to rail transit and LRVs. Having different types of vehicles with different weights, crashworthiness, and braking characteristics commingling on the same track imposes safety concerns. As stated in TCRP 52 [30], emphasis in North America is focused on rail safety and collision survival, versus European emphasis on collision avoidance and impact attenuation. For example, railroad buff strength for overseas railroads is in the 300,000–400,000 lb range, while North American railroad requirements are twice that, at 800,000 lb. Typical light rail car buff strength generally is 200,000 lb or less, and rarely, if ever, more than twice the empty weight of the LRV such as CPUC General Order 143-B. Making rail cars stronger to sustain collision

forces creates a heavier car that is unable to stop in shorter distances, thereby increasing costs and power consumption, while sacrificing performance.

Related to the scarcity of North American main line railroad electrification is the potential reintroduction of Diesel Multiple Unit (DMU) rail car to North America. DMUs are similar to LRVs in appearance and performance, except that they can operate independently of wayside traction power infrastructure. New Jersey Transit's River Line is among the first contemporary uses of the light DMU technology as a surrogate for conventional electrified light rail. Analysis indicates that DMU can offer both cost savings and operating advantages.

Operating trains that travel at different speeds reduces capacity on a rail line. The optimum condition can be achieved by operating at about the same speed by all types of trains. All other things being equal, the longer the block length, the lower the capacity. The block length is based on the distance it takes to stop the train. Braking distance varies by the train type. Signal design would have to conform to conventional freight railroad requirements, but also accommodate design elements unique to LRV. For example, freight trains require much greater braking distances than do LRVs, so the design must consider the longer freight braking distance when establishing the signal block layout and establishing speed limits for the various classes of trains to operate over a line. However, longer signal blocks unnecessarily penalize LRVs by causing them to run at reduced speeds under certain signal aspects. This scenario could be compounded under certain topography, such as downhill or grade crossing territories. Special operating rules must therefore be developed to help reduce or eliminate such penalties.

Under the general guideline of the "Joint Statement of Agency Policy Concerning Shared Use of General Railroad System by Conventional Railroads and LRT systems" (Joint Policy Statement) issued in 2000, FRA does not consider the situation, where a rail transit line shares a common right-of-way with a general railroad without sharing track, involves shared use of the general system by the rail transit line, therefore a waiver is not necessary. Where a rail transit line shares track with general railroad, but under strict "temporal separation" as referred in the Policy Statement, the FRA is likely to waive many of its rules. However, the petitioner must demonstrate that its system program and state safety oversight program addresses all relevant safety issues.

For commingled operations on shared track, the petitioner will face a "steep burden" of demonstrating measures taken to reduce likelihood of collision between light rail and conventional equipment, because of concerns over major differences between FRA-compliant cars and light rail vehicles (LRV). It seems that, in this litigious society, chances are slim for winning approval of such waivers from FRA.

In North America, liability is the single biggest institutional obstacle to joint operations between rail transit and freight railroad. In spite of many concerns arising from joint operation, one of the primary fears is a catastrophic event resulting in major loss of life and property damage. Thus, an important condition for a freight railroad to share its track with rail transit is to be held harmless, regardless of fault.

According to General Accounting Office [32], in 1997, Congress limited the aggregate damages that may be awarded to all passengers claims from a particular rail accident to $200 million and permitted providers of rail transportation to enter into indemnification agreements. After reviewing the legislation, the GAO concluded that the liability cap applies to commuter rail operations, which is certainly a good base for commuter service providers to cap their liability insurance to under $200 million per accident. It seems unlikely that such a cap will apply to LRT as well, since LRT is non-FRA compliant.

The level of risk can influence the level of liability. As risk increases, the necessity for liability insurance coverage increases too. Where passengers are involved, risk increases dramatically and liability insurance can become excessively onerous. No freight rail owner is willing to risk the assets of its railroad, but looks for return on investment to find joint operations attractive. Higher risks for passenger operation create a dilemma for transit operators.

Potential Solutions

It is understood that successful experience from overseas cannot be directly transferred to USA because of cultural, regulation, intuition, and physical differences.

However, certain risk mitigation choices can be applied to get USA prepared for future possible commingled operation.

Advanced signal systems, positive train control, or Intelligent Transportation System (ITS) may be applied to improve the efficiency and communication of rail transit. Railway signal systems, in general terms, are made up of block signal system, interlocking systems, and control systems. Block signal systems are designed to inform operators of the need to stop when there is danger of rear end collision. Block lengths are based on the distance it takes the heaviest train to stop. To accommodate disparate operational trains on the same tracks, block signal systems need to be reconstructed to assure the appropriate block length based on the train's speed, braking ability, weight, etc. Automatic cab signaling (ACS), displaying signal aspect information on the operator's control panel, can be used to reduce the possibility of operators missing signals. Further, positive train control systems, including automatic train stop (ATS) and automatic train control (ATC), can take control of the trains if operator does not take appropriate actions upon receiving the signals. The US government requires that for operations above 79 mph, cab signaling or train control systems are installed and used. In addition, all railroad lines carrying passengers must be equipped with an acceptable system of Positive Train Control (PTC) by 2015, as required by the recently enacted Railroad Safety Improvement Act (RSIA, 2008).

Interlocking signals prevent trains from colliding where railroad tracks meet. All interlockings for commingled operations should be designed to ensure that they do not delay trains or cause capacity problems. Centralized traffic control (CTC), commonly used on busy railroads, allows trains to be routed through complex track networks to optimize performance of the overall railroad system. A CTC system allows the dispatcher to safely direct overtaking trains traveling in the same direction and trains meeting in opposite directions. This enables the dispatcher to place a train in a siding or on an additional mainline track, to avoid delay [33].

As described earlier, its punctuality, superb service, and the large crowds of people using it characterize Japanese public transportation. The German rail system is also credited with convenient, on time, superb service. Both systems are the envy of the world. Such success is achieved not only by innovative technologies, but also by good communication, understanding and attitudes among the parties sharing the facilities.

A sophisticated operational plan can be worked out between willing parties. Communication must be established and maintained between the operational managers. Since passenger and freight operations have different operating characteristics, employees from a transit background may not be familiar with freight rail operation and vice versa. Thus, it is important for professionals from both parties to reach a mutual understanding, not only the dispatchers.

Insuring a high standard of employee qualifications and performance is important in commingled operations. Cross training might be helpful to enhance mutual understanding of employees in both operational environments. One of the transit agencies suggested, "Get transit agencies to understand the nature of freight rail business. Get freight railroads to understand the requirements for public funding of transit projects, lengthy time, many steps, public review and comment, etc."

According to a recent TCRP study [3], "Fail-safe" means that any foreseeable failure will result in the system reverting to a safe state. This approach works well for mechanical and electromechanical devices, but has proved very difficult to apply to the programmable processor-based systems that have been coming into use over the past 10–15 years. New safety assurance methods and procedures have been developed for application to safety-critical electronic systems and software and related installation and maintenance activities.

There are a number of train control systems that ensure that trains sharing track do not collide [3]. These systems override the vehicle operator in the event of a signal violation that could result in a collision with another train. A list of various approaches to provide fail-safe train separation in approximate order of their common use is highlighted here but detailed information on each should be referenced in the TCRP Report No. 130 [3] and other engineer publications:

- Automatic Train Stop (ATS)
- Train Protection and Warning System (TPWS)

- Indusi "Punktförmige Zugbeeinflussung" (PZB)
- Automatic Train Control (ATC)
- Communication Based Train Control (CBTC)
- Positive Train Control (PTC)

Three federal agencies, FRA, FTA, and Surface Transportation Board (STB) govern different aspects of railroad operation. FRA focuses on safety; FTA controls funding to transit projects; and STB is responsible for economic regulation of railroads. However, none of these agencies has responsibilities and authority to facilitate transit systems on freight track access issues, leaving transit agencies who desire for a commingled operation in a difficult situation when negotiate with railroad companies. The difficulties create a discouraging effect on the development and expansion of commuter rail and light rail transits. Therefore, an affiliate agency should be established to provide guidance or facilitate the negotiation on track access. The Rail Transit Safety Initiative recently submitted by Secretary LaHood [34] has the potential to empower the safety oversight and facilitate shared-use issues. However, detailed programs and procedures are still under development and their impact on shared use remains to be seen.

FTA and FRA issued Joint Statement to "coordinate the use of respective safety authorities with regard to shared-track operations." However, the waiver program restricts the opportunity to commingled operation since it is a strict and tedious review process. FRA officials are cautious to say "yes" to commingled operation. Though the technologies are sophisticated and plenty experience has been gathered from overseas, no one can guarantee 100% safety and no one can afford the blame of permitting the commingled operation. It is safe to assume that not only concerns over operation safety, but also concerns over public reaction and political impact are important in the FRA decision making.

The objectives of the business model are to establish the core operational requirements essential in order to satisfy oversight agency's concerns for retention of an equivalent level of safety for joint freight/LRT service operations [35]. The business model addresses the spatial, temporal, and institutional changes associated with sharing track by freight and noncompliant passenger vehicles without temporal separation. It will also highlight strategies to deal with incremental risks and liabilities associated with commingled operations.

It is a challenge to develop a business model of commingled operations since there are no domestic cases of "commingled" operations of freight and non-FRA-compliant passenger services, and the number of cases where freight and light transit equipment share tracks on a temporal separation basis is limited. On the other hand, greater opportunities may be created since there are many domestic cases where public passenger transportation and private freight operations share track, and there are many proven international experiences in commingled operations of LRT and freight services [35].

As pointed out by Transportation Research Board [29], the noncompliance, exemption, and buff strength requirement are largely developed based on the American mentality, similar to larger SUVs on the road. That is, if you drive a larger car or heavier train, your damage would be less when an accident happens. On the other hand, the European philosophy relies on accident avoidance, that is, all parties try their best to avoid collision and other accidents altogether. The philosophical difference may serve as a fundamental reason for Karlsruhe, Germany being safely and efficiently operated for years while its American counterpart cannot even pass the pilot stage.

Judging from the current extensive discussion of the shared issues, newly commissioned studies by GAO [32], FRA [2, 19], NJ Transit [1] and TCRP [3], it can be safely predicted that the interest on shared track or commingled operation has been reawakened. Along with the increasingly widespread interest, a pilot program could develop a realistic framework to explore the potential of commingled operations.

Based on the obvious safety concerns, capacity expansion and cost savings are also main factors driving commingled operating practices. Before any commingled operation may be even tested, a thorough cost-benefit analysis coupled with a realistic operation analysis should be conducted. A detailed risk assessment should also be performed and a set of performance measures should be developed to benchmark and mitigate the risks.

Future Directions

Interest in LRT as a viable urban transportation system has been growing worldwide and new LRTs are appearing on urban streets in many countries. Pressed

with a growing demand for extended LRT services, a few LRT agencies seek the possibility of applying overseas experience in USA. After examining existing practices in the USA and overseas, it is hoped that this entry has highlighted that commingled operation has many advantages, including, but not limited to reduced construction costs, increased track usage, and quicker new starts. With strict train scheduling and on-time performance control, the commingled operation proves to be viable overseas. Japan and some European countries, especially Germany pioneered in commingled operation between LRT and freight railroad. However, many issues need to be resolved before the USA can realize similar implementations.

Building on the current knowledge base and momentum on transit demand under the large economic background, it is foreseeable that multiple fronts will be advanced along the lines of technology improvement, regulation changes, and business model development to promote shared use of railroad infrastructure between LRT and freight railroads. A logical next step may be a pilot model to address all these issues in a confined but realistic environment.

Acronyms

ACS	Automatic Cab Signaling
ADA	American with Disabilities Act
APTA	American Public Transportation Association
ATC	Automatic Train Control
ATS	Automatic Train Stop
CBTC	Communication Based Train Control
CFR	Code of Federal Regulation
CN	Canadian National
CTC	Centralized Traffic Control System
DMU	Diesel Multiple Unit
FHWA	Federal Highway Administration
FRA	Federal Railroad Administration
FTA	Federal Transit Administration
GAO	Government Accountability Office or General Accounting Office, prior to 2004
ICE	Intercity Express Train
ITS	Intelligent Transportation System
JNR	Japanese National Railways
JR	Japanese Railways
LRT	Light Rail Transit
LRV	Light Rail Vehicle
MBTA	Massachusetts Bay Transportation Authority
MTA	Maryland Transit Administration
MTDB	Metropolitan Transportation Development Board
NCTD	North County Transit District
NJ TRANSIT	New Jersey Transit
PTC	Positive Train Control System
PZB	Indusi "Punktförmige Zugbeeinflussung" System
ROW	Right-of-Way
RSIA	Railroad Safety Improvement Act
SDTI	San Diego Trolley Inc.
STB	Surface Transportation Board
SWG	Shared-Use Working Group
TCRP	Transit Cooperative Research Program
TPWS	Train Protection and Warning System
TRB	Transportation Research Board
UTA	Utah Transit Authority
VTA	Santa Clara Valley Transportation Authority

Glossary

Average speed The speed that results by dividing the round trip time of a transit vehicle to traverse a transit route from beginning to end and back to the beginning, including the layover time until the beginning of the next trip, by the roundtrip length of the route. Average speed also may be calculated by dividing annual vehicle miles for a route by annual vehicle hours for the route. Average speed is slower than scheduled speed because average speed includes layover time at each end of the route.

Bus rapid transit An application of buses in a way that emulates rail transit. Bus rapid transit usually provides for a reserved right-of-way for buses that includes wayside stations. Fare collection systems allow passengers to board and alight buses at all doors. Drivers are not involved in fare collection. Buses usually are articulated and contain several wide doors, all of which open when buses stop at online stations. Rights-of-way are usually Type A or B, and scheduled speeds of 20–25 mph are possible.

CBD Central business district. The CBD typically is the largest business center in a metropolitan area and often dates from the streetcar era. At one time, CBDs contained almost all jobs, shops, and recreation in metropolitan areas, but since World War I when autos became the principal form of urban transportation, CBDs have been in relative decline as most job, shopping, and recreation growth has occurred in the suburbs.

Commuter rail A form of rail transit in which transit vehicles use the same tracks (or have the capability of doing so) as do long distance freight and passenger trains. Commuter trains usually are comprised of several large cars containing closely spaced seats and two or three wide doors on each side of the car to allow rapid boarding and alighting of passengers. Commuter trains can be electrically or diesel powered and may be either pulled by locomotives, or have each car equipped with electric motors or diesel engines under the floor. Conductors typically collect fares from passengers while the trains are in motion.

Edge city One of several terms used to describe large urban centers in metropolitan areas that rival central business districts in magnitude and diversity of employment. Edge cities typically cover a much larger area than CBDs, however, with much of the land devoted to parking lots and high-speed, multilane roads. It typically is difficult or impossible to walk from one part of an edge city to another part.

Express bus A form of bus transit in which buses run nonstop over much of their routes. The most typical application is for express buses to run during weekday rush hours between outlying affluent suburbs and the metropolitan CBD. In the morning express, buses typically circulate through neighborhoods in which affluent commuters live, and when they fill up the buses travel nonstop on a reserved freeway lane or sometimes on a specially built busway to the edge of the metropolitan CBD. The express buses may use purpose-built ramps to gain access to or to leave their freeway lanes. Express buses then circulate through the CBD on city streets to distribute their passengers. In the afternoon peak period, express buses retrace their path to the suburbs. Most express bus routes offer a handful of

one-way inbound trips in the morning and one-way outbound trips in the afternoon. Passengers pay their fares to the driver.

Grid route structure A multidestination transit routing method, in which each north–south and east–west arterial road in a metropolitan area has its own bus, streetcar, light rail, or heavy rail route, typically providing frequent service. To travel from one part of a metropolitan area to another, passengers typically walk to a nearby bus or streetcar line, travel to a connecting route, and alight near their final destination. Grid route structures afford passengers the ability to travel from any place to any other place in a metropolitan area without out-of-direction travel, but grid route structures require most passengers to transfer. Grid route structures typically attract much higher passenger volumes than radial transit route structures and are more productive, as well.

Heavy rail The word "heavy" refers to heavy infrastructure that is associated with subway and elevated rapid transit lines. Heavy rail lines are exclusively Type A rights-of-way achieved by directing the paths (or grades) of rail transit lines above or below paths (or grades) of conflicting transportation. Thus, heavy rail is also called, "grade-separated" transit. Typically, heavy rail is operated by trains of up to ten electrically powered cars, each car having two or three wide doors on each side. Stations are designed to be as long as the longest trains, an expensive proposition when, as is typically the case, the entire station is buried far below the surface or erected far above ground. Passengers pay fares at turnstiles or elaborate and expensive fare collection machines before boarding trains.

Interurban A nearly extinct form of US rail transit in which lightly built electric rail lines connected more densely populated rural areas with nearby towns or cities. Lines typically were 15–40 miles long, but both shorter and longer lines were built. The longest through interurban run was from Detroit to Cincinnati, a distance of over 300 miles. Typically, interurbans entered city centers over the tracks of local streetcar companies, but they operated through the countryside either alongside state highways or across county on their own rights-of-way. Interurban cars stopped frequently and offered scheduled speeds typically of about 20 mph. Interurban cars were the size of smaller mainline railroad coaches but typically each car was electrically powered, using streetcar technology. Interurbans usually operated as one-car trains but could operate in multicar trains controlled by a motorman in the lead car, much as rapid transit trains. Interurban lines appeared in the USA during the decade before the automobile appeared and spread rapidly. They declined just as rapidly after World War I and with a few exceptions disappeared before the USA entered World War II.

Light rail "Light" refers to light infrastructure and not to the weight of the rail or of the cars. Light rail evolved from streetcars in northern European cities in the three decades following World War II and is characterized by short trains of high-capacity rail cars operating though metropolitan areas on mostly Type B rights-of-way. Each train has multiple wide doors, and light rail systems employ fare collection systems that obviate the need for employees to be on trains to collect fares. Passengers board and alight at all doors. Light rail lines are intended to function like heavy rail lines but at a much lower capital cost. In the USA, they are most effective where they are configured as long routes up to 30 miles long, along which are situated major destinations. Scheduled speeds typically are in the range of 19–30 mph in contrast to typical local bus speeds of 10–15 mph. Bus routes are reconfigured from CBD-radial service to light rail stations at major destinations in the suburbs, thereby creating multidestination transit systems with improved productivity. Metropolitan transit networks having such characteristics are among the most successful in the USA and Canada.

Mode A type of transportation technology, such as the walk mode, the auto mode, the bus transit mode, or the rail transit mode.

Multidestination transit route networks A transit network so structured that users can reach many destinations in a metropolitan area while avoiding out-of-direction travel. Doing so usually requires a transfer, however. A grid network is one type of multidestination network, but not the only type. Multidestination transit systems stand in

contrast to radial transit systems, where most transit routes radiate outward from the one destination that is deemed the most important to serve, usually the CBD.

PCC Streetcar A streetcar developed by the Presidents' Conference Committee (a committee of the presidents of US and Canadian streetcar companies) between the late 1920s and mid-1930s. The objective of the development was to create a quiet and smoothly riding streetcar that could accelerate and decelerate as rapidly as autos in stop-and-go traffic while not jerking standing passengers off their feet. The PCC car, particularly its control system, is considered one of the marvels of North American industrial engineering, but a streetcar that was like a bus on rails competing with the auto in its own environment was not what was needed to save the transit industry.

Proof-of-payment (POP) Fare Collection System Passengers are required to determine what their fare for a particular trip should be and to then purchase a ticket for that trip before they board the vehicle. They may board any door. Nobody on board monitors fares while passengers board, but roving inspectors may ask for proof of payment at any time. Passengers without valid proof are warned or fined. Managers typically employ a sufficient number of inspectors to inspect 1% or 2% of passengers. The percentage of passengers without valid proof of payment is the fraud rate, which is generally lower than that of driver-administered fare systems. Its chief advantage is allowing passengers to board at all doors, important for high-capacity lines but not important for low patronage bus lines. Most passengers using such systems buy monthly, weekly, or daily passes. Passengers buying 90 min passes may do so at simple vending machines on train platforms.

Radial transit route systems Most transit routes radiate outward from the one destination that is deemed the most important to serve, usually the CBD. Passengers are given a one-seat ride from their homes to the CBD. Underlying a radial route structure is the belief that passengers will not transfer. Radial route systems stand in contrast to multidestination route networks (of which the grid network is an example). Most radial transit systems in the USA are characterized by falling demand and productivity. They typically have higher operating costs per passenger mile than multidestination networks.

Rapid transit The traditional name for what now is known as heavy rail.

Scheduled speed The speed that results by dividing the length of a route by the time that it takes for a transit vehicle to travel from the beginning to the end of the route. Scheduled speed is much slower than the top speed at which transit vehicles operate, because scheduled speed includes time spent at stops, acceleration and deceleration time (which is what transit vehicles are doing much of the time – hence the design objective of the PCC car), and it includes time lost in traffic congestion. Scheduled speed is faster, however, than average speed, because the later includes the layover time at each end of the route.

Streetcar An electrically powered rail transit vehicle, in North America traditionally about 40 ft long and 8 ft wide. Streetcars historically ran on tracks imbedded in the middle of streets, and they competed for street space with vehicular traffic. Thus, they ran on right-of-way type C. Passengers board and alight from streetcars in the centers of streets, sometimes on raised concrete islands. In North America, streetcars typically operated with two-person crews, a motorman to drive the car and a conductor to collect fares while the car was in motion. PCC cars, which appeared in the mid-1930s, were operated with foot pedals that left the driver's hands free to collect fares, enabling one-person operation.

Traction Until the 1920s, streetcar and interurban companies were known as traction companies. One still hears the term, "electric traction."

Transit-oriented development, or TOD A type of development advocated by many planners but not often seen that is comprised of dense, clusters of various types of housing units, retail stores, restaurants, bars, and offices clustered within a quarter of a mile of a transit stop, preferably a rail station. TODs also are characterized by pleasant pedestrian paths linking all of their parts with each other and with the transit station. Studies of the behavior of residents of and visitors

to TODs indicate that most use automobiles but that a significant minority do in fact use transit. TODs built to date usually have large parking structures as well as transit access.

Transit The generic name used today in the United States for fixed-route, scheduled public transportation services, whether they are bus or rail. One may speak of transit agencies, rail transit, bus transit, or just transit.

Trolley bus A bus powered by electricity delivered to the vehicle by overhead wires. Upward-sprung dual trolley poles (one for positive current and the other for negative current) connect with dual parallel overhead wires strung above the street. Trolley buses may travel in the traffic lane under the wires, or they may travel in lanes on either side of the lane under the wire.

Vehicle miles traveled (VMT) An automobile or light truck traveling 1 mile. VMT is the standard unit for measuring the magnitude of auto use in a metropolitan area.

Verkehrsverbund or federation of transit operators A form of transit organization used in several German metropolitan areas. The Verkehrsverbund is characterized by separation of ownership of transit services in the metropolitan region among many different transit operating companies or agencies, and coordination between all of the transit services in the region through a small, centralized public marketing and planning body. Passengers may navigate transit routes throughout the metropolitan area without being aware of boundaries between different transit operating agencies. The idea behind this form of organization is that smaller operators may control their timeliness as well as their operating costs far better than large operating companies, while a central coordinating body insures coordination among all operators through scheduling, fares, and provision of information. The San Diego MTDB created and ran this form of organization from about 1979 to 2003 and experienced better coordination between its various transit services and lower costs per passenger mile than any of the large public transit districts in the USA. It also experienced among the highest rates of passenger growth during this period.

Definition of the Subject

Light Rail Transit

Light rail transit is one of several forms of rail public transportation designed to transport passengers within metropolitan areas, but there is no agreement on its precise definition. The Transportation Research Board of the National Academy of Sciences [1] and the American Public Transportation Association [2] define light rail to include streetcars and tramways. Both organizations also define light rail to include modern metropolitan rail systems characterized by multicar trains operating on tracks that are segregated from motor vehicle traffic except at cross streets. Vuchic [3] defines light rail with respect to the nature of metropolitan rail right-of-way that it uses. He categorizes metropolitan rail rights-of-way according to three types. Type A denotes grade-separated rail rights-of-way that have no conflicts with motor vehicle, other rail, or bicycle and pedestrian traffic. Type A rail rights-of-way characterize subway and elevated rail rapid transit lines in the world's cities. Type B denotes rail rights-of-way where rail vehicles are segregated longitudinally from motor vehicle traffic, bicycles, and pedestrians but have conflicting traffic crossing tracks at cross streets. Type C denotes rights-of-way where the tracks are imbedded in streets shared by motor vehicle and/or pedestrian traffic, and rail vehicles have no preference over other vehicles with which they compete for road space. Traditional streetcars and trams, characterized by the operation of single rail cars in mixed traffic with drivers collecting fares, are associated with right-of-way Type C. Vuchic associates light rail transit primarily with right-of-way type B, upon which short multicar trains operate with fare systems allowing passengers to board at all doors [4]. Vuchic's definition gives light rail much higher level of service, measured in average speeds and passenger-carrying capacity than streetcars and trams (typical scheduled speeds of 10–14 mph), but lower speeds and passenger-carrying capacity compared to subway and elevated rail rapid transit lines (scheduled speeds of 20–45 mph), whose long trains use Type A rights-of-way. According to Vuchic's definition, the cost of constructing light rail often falls between the high cost of constructing subways and elevated lines and the much lower cost of constructing streetcar lines.

Vuchic's definition for light rail is closely aligned with the historical rise of light rail transit in the 1950s, 1960s, and 1970s as a reform mode of metropolitan transportation that addressed shortcomings of traditional streetcars and trams as they succumbed to local bus replacements in city after city throughout the world [5, 6]. Political leaders in many cities wanted a form of urban public transportation that provided faster, higher capacity, and more productive service than traditional streetcars or local buses but that cost less than subways or elevated railways that only the largest cities could afford. Light rail, and more recently bus rapid transit, evolved to fill unmet demand in many medium-sized metropolitan areas for a transit mode offering intermediate capacity.

This entry follows Vuchic's definition for light rail. It defines light rail as the operation of short trains operated with only one person. The trains have many large doors, any of which passengers may board at stops. Drivers are not involved in fare collection. Light rail trains operate primarily on right-of-way Type B, though they have the flexibility to operate over rights-of-way Types A and C. Some segments of a light rail system may exhibit all of the features of a completely grade-separated metro line, while other segments have lower-speed, at-grade operation. Selective investment based on need in specific areas is a key characteristic. What is "light" about light rail is the overall average level of capital investment per unit length of a route; the term does not pertain in any way to physical weight.

Generally, light rail trains operate at faster scheduled speeds (18–30 mph) than either streetcars or local buses and provide higher passenger carrying capacity, as well. Light rail systems also carry more passengers per employee than buses or streetcars.

The intent of light rail construction is to attract more passengers to transit by providing a quality of transit service that approaches what metropolitan subway or elevated rail rapid transit lines could achieve in particular corridors but at a much lower overall capital cost. In some metropolitan areas, the intent of investing in light rail also is to improve the productivity of the transit system by replacing numerous duplicative bus routes running to the central business districts of cities with one or two light rail lines to which passengers transfer at outlying stations. In such cases, transit operators restructure shorter bus routes to suburban light rail transit stations: because buses meet trains at the same time, they also connect with each other, and therefore also make intra-suburban transit usage more feasible. The intent is that fewer bus and train car miles will be more aligned with dispersed travel demands in today's decentralized metropolitan regions, thus attracting more passengers, resulting in more passengers per employee and lower operating cost per passenger. In recent years, some political leaders also have intended light rail investments to attract new urban development to the vicinity of light rail stations.

Viability

To measure viability of light rail transit is to measure how well light rail investments achieve their objectives. Following on Fielding's treatment of transit performance measurement [7], this entry evaluates how light rail investments change overall transit performance in the metropolitan areas where the light rail investments are made compared to similar metropolitan areas where light rail investments are not made. In general, the entry examines trends in metropolitan transit ridership per capita before and after light rail as a measure of light rail's effect on transit ridership in the region. It examines trends in ridership per transit vehicle mile over the entire region as a measure of productivity. It examines regional transit operating expense per passenger or passenger mile as a measure of efficiency. Where results of onboard passenger surveys of passenger characteristics are available, this entry also reports those. The entry also examines how light rail has affected development in the areas that it serves by referencing academic studies on that topic.

Introduction

Light rail transit evolved from streetcars in northern European cities during the 1950s and 1960s. It was what resulted as transit operators incrementally modified their traditional streetcar systems to survive mass motorization and rapidly rising wages. Light rail was characterized by one driver (with the assistance of no other labor) operating a short train comprised of large articulated streetcars with numerous wide doors, fare collection systems allowing passenger to enter and leave all doors, and segregation of trains from

automobile traffic. Light rail was much more productive than buses and proved to be a more successful adaption of streetcars than the earlier American approach to saving streetcars from auto and bus competition. The American approach was based on developing a single unit streetcar about the size of a bus whose performance mimicked that of automobiles, with which streetcars competed for street space. Plagued by congestion from passengers forced to board front doors to pay their fares to the driver, as well as by auto congestion, the American approach resulted in at best marginal productivity superiority over buses. It failed to save streetcars in most US and Canadian cities.

The European light rail idea, carried on the wings of Canadian and US urban advocates and transit reformers, was first adopted in a North American city in 1978 when Edmonton opened a light rail line and restructured buses around its stations, 27 years after it converted its last streetcar line to bus operation. Edmonton's sister city, Calgary, opened its first light rail line in 1981. The US transit industry resisted the light rail idea, but reformers forced transit systems to adopt light rail, first in San Diego in 1981, followed by Portland, San Jose, and Sacramento in 1986–1987. The US Urban Mass Transit Administration (UMTA) sponsored the opening of a demonstration light rail line in Buffalo in 1984 with the full cooperation of the transit system in that city. The next line opened in Los Angeles in 1990, and 12 additional metropolitan areas added light rail lines since then. Many of the metropolitan areas that opened initial light rail lines since have expanded their systems. Some of the North American streetcar lines that survived into the 1970s also have been rebuilt with some light rail characteristics.

Light rail advocates hoped that light rail investments would reverse the fortunes of declining North American transit systems. Some hoped that the investments would do the same for declining downtowns and inner city neighborhoods. Some actually hoped that light rail combined with renewal of urban centers could displace autos as the main form of urban transportation. Actual results have been mixed. Some light rail investments, such as in San Diego, Portland, and St. Louis, have had highly positive impacts on the performance of transit in their metropolitan areas. Others have had little positive impact. Some have been accompanied by greater population densities and more walkable environments. None, however, has reduced significantly the dominance of automobiles as the primary mode of urban transport.

The purpose of this entry is to explain why results are mixed, and in particular to understand what light rail innovations are most effective for better transit system performance. It does this by first explaining how streetcars arose and affected the growth of North American cities before World War I. It then examines reasons for streetcar decline, efforts to stem the decline, and reasons why those efforts failed. It then explains how light rail arose as a fix for streetcar defects, how and why light rail was adopted in various North American cities. The analysis of light rail performance in various US metropolitan regions precedes the entry's conclusions.

Historical Background

Light rail is not synonymous with streetcar (or tramway in English parlance); it is more accurate to see light rail as a mode that evolved as a reaction to shortcomings of streetcar technology and applications. This section makes that evolution understandable. It provides a history of the North American streetcar beginning with a depiction of its technology and how it influenced the form of American cities before World War I. It then considers the streetcar's increasingly apparent shortcomings as auto use intensified, urban form changed, and city bus technology improved. The history considers the American and Canadian transit industry's attempt to modernize the streetcar with new technology in the 1930s (the famous PCC car), and it considers reasons for the failure of that effort, including the American auto industry's involvement in liquidation of American streetcar systems. Finally, it considers the appearance in the postwar period in western Germany of a different, more successful approach to modifying streetcar technology that is known as light rail.

The American Streetcar at the Peak of Its Influence and How It Shaped the City

From 1888 when Frank Sprague implemented the world's first successful streetcar system in Richmond, Virginia through the 1920s, the electric streetcar

symbolized the American transit industry. In cities throughout the country the press followed the expansion and financial scandals of the traction industry, "traction" being the term that the public then used for streetcars. Land owners on the fringes of cities clamored to have traction lines extended to their lots, thereby making the lots much more valuable. In as little as 30 min and for a nickel fare (a fare the middle class could afford), streetcars operating at average speeds of 12 mph could connect lots in the countryside with jobs and opportunity in the center. Such relationships stimulated a huge demand for suburban living, and to meet it, traction lines, sometimes owned by real estate interests, expanded outward in all directions. Population followed. For the first time in their histories, the horribly overcrowded cities of America began to empty outward in the form of new streetcar suburbs, built on previously empty land around the city edges. The center cities from which the middle and working classes fled changed as well, as department stores, specialized shops, corporate offices, financial firms, hotels, theaters, concert halls, and other less reputable types of entertainment rushed in to fill the voids left by the departing middle and working classes [8, 9].

By the 1910s, the streetcar created a new American city characterized by specialized sections. Iconic was the fashionable Central Business District, a vibrant area with specialized subdistricts wherein were located almost all jobs and activities that the middle class wished to reach. Poorer groups remained in cheaper, older housing surrounding the new center cities. Factories and warehouses also remained packed around railroad yards. Further out, extending along the electric car lines, were the new streetcar suburbs. These were middle and working class bedroom districts, each a new homogenous enclave catering to a specialized income and ethnic group. Every day the middle and working class populations surged into the center on electric cars and surged outward in the evenings. Wives and children filled the cars during the middle of the days, and in the evenings and Sundays families used the cars for recreation. For the middle and working classes, the streetcar revolutionized the American city and the way in which they experienced it [8–10].

The streetcar evolved to efficiently fulfill the mass transit role called for it. By the 1910s, the modern streetcar was about 40 ft long and 8 ft wide, riding on two four-wheel trucks. Each axle was driven by its own electric motor that was suspended from the axle. Air pressure controlled the braking power. Cars typically had top speeds of about 30 mph. A cabin (saloon) in which passengers rode constituted about two-thirds of the length of the vehicle. On cars operating in clement climates, cabins often were divided into a weather-protected section and an open-air part. The rest of the length typically was comprised of large platforms projecting from both the front and rear of the car. The platforms, which were lower to the ground than the center sections, contained large doors and vestibules from which passengers could board and alight. The driver, called a motorman, stood at the controls on the front platform, and the conductor, who collected fares, stood on the rear platform. The conductor communicated with the motorman with bells that he (rarely she in 1910) could activate by an overhead cord. Terms like, "platform employees," or, "platform hours," still are used by some transit systems today to denote transit operating personnel (usually bus drivers) and the hours that they work serving the riding public [8]. Figure 1 shows a state-of-the-art streetcar from this period.

In operation, the streetcar was a crowd-eater. Coasting into a stop thronged with waiting passengers, the streetcar's gaping rear door beckoned the crowd to board. As the last passenger cleared the steps, the conductor gave two quick yanks on the bell cord to the motorman, who replied with two loud clangs on the car's traffic-warning brass gong affixed to the front. The car lurched forward, and the conductor then collected fares as the car swayed and trundled along to its next stop, often interrupted by traffic congestion and furious bursts of clangs from the motorman's gong. As passengers paid their fares, they proceeded forward into the cabin to find a seat. Those not finding a seat stood in the aisle holding onto leather straps hung from the ceiling, or they stood on the front platform, from which they ultimately alighted. Cars from this period were not fast, but despite the huge crowds they ingested and disgorged, they did not lose time at passenger stops, because large numbers of passengers could board quickly – and fare collection occurred while the car was under way. They truly were mass transit vehicles [8].

Light Rail Transit, Systemic Viability. Figure 1
Traditional American streetcar. San Francisco Municipal Railway Car No. 1, dating from 1912, in a neighborhood it helped to create. Author's photo, taken in 1981

The Decline of the American Streetcar Beginning During World War I

Several factors began the streetcar's long decline around World War I. Most immediately, the cost of labor and supplies more than doubled during the war, while streetcar companies often found it politically difficult to raise the fare above the accustomed nickel, sometimes written into corporate charters in the 1890s. Profits turned to losses, and investment in tracks and streetcars dwindled commensurately. Companies by and large stopped extending lines to undeveloped areas demanded by developers, and service became less frequent and more overcrowded [11].

Beginning about 1910, automobile registrations also climbed rapidly. Auto ownership initially rose fastest in rural areas, but by World War I automobiles were widely distributed in cities, as well. House builders began shifting their products from clients using streetcars to clients using autos. In cities throughout the country, developers by World War I were offering homes in areas not served by streetcars, though they still were using their political muscle to attempt to force streetcar companies to extend lines into new territory. By 1925, however, housing developers no longer cared whether streetcar companies extended lines into new territory. Streetcars had become irrelevant to them [11].

At the same time, motor trucks cut the tether between retailing and railroad yards and led to the extraordinarily rapid decentralization of retailing. Horse-drawn wagons were slow and expensive, and in the pre-truck era, retailers could not afford to locate their stores beyond a short wagon haul away from the giant merchandise warehouses adjacent to the rail yards. Almost all retailing was in the CBD. With the adoption of trucks, however, retailers of all stripes decentralized. The driving force was demand for free parking from the increasingly large number of customers who came downtown to shop in their autos. Retailers quickly learned that the cheapest solution to the parking problem was building major branch stores, which could be easily supplied by truck from the central city warehouses. By 1925, many established CBD-located firms were opening new stores in the suburbs that were grander and more posh than their original CBD flagship stores. The new stores all were built around auto access and free parking. The highly centralized, streetcar-oriented retailing regime

characteristic of the American city in 1910 had given way by 1925 to a decentralized regime characterized by rampant suburban strip retailing and free parking. Already planners were talking about the decline of the CBD [10, 12].

The combined weight of these forces pushed down streetcar patronage during the 1920s in all but the largest cities, and even there streetcar riders became increasingly dominated by those going to and from work. The smaller the city, the more rapid was the loss of streetcar traffic [11]. Streetcar companies began abandoning lightly used streetcar lines and replacing other lightly used lines with buses.

Revolution in Streetcar Technology: The PCC

Most traction industry leaders thought that streetcars would continue serving the more heavily traveled lines, however, and toward the end of the 1920s, they formed the Presidents' Conference Committee to develop a super streetcar to reequip the "trunk" lines. The committee was comprised of presidents of various streetcar companies and had at its disposal the best electrical engineering talent from the larger operating companies as well as from the streetcar manufacturing companies. The result was the Presidents' Conference Committee car, or PCC car, which was unveiled in 1936, and which is considered today to be one of the marvels of American industrial engineering. Figure 2 shows a train of two PCC cars coupled together in Toronto. More than 5,000 PCC cars were built between then and 1952 for US and Canadian application, and even more were built for foreign use. Despite the car's success as a piece of industrial engineering, however, it failed to save the North American streetcar industry [8, 13].

In the PCC car, the traction industry sought and obtained a streetcar that could keep up with autos in stop and go traffic. The PCC with a full standing load of passengers could accelerate smoothly and silently from a stop as fast as an auto, and it did so without jerking, an important consideration given that many of the

Light Rail Transit, Systemic Viability. Figure 2
Two PCCs coupled together into a train in Toronto in 1974. There is a driver in the second car, as well, to collect fares and transfers from boarding passengers, who are allowed to board only at the front doors of each car. Note passengers queuing at front doors of both cars to pay fares. Also note sign on signal pole prohibiting motorists from turning, so as not to impeded streetcars. Finally, note the illuminated white sign just to right of the streetcar, indicating a subway entrance. This spot was (and remains today) an important transfer point between the north–south Yonge subway and east–west Queen streetcar in Toronto's gridded route network. Author's photo

streetcar passengers were standees. It also could brake to a smooth stop just as rapidly. Although its initial rate of acceleration of about 3.5 mph per second fell off rapidly as it gained speed, the PCC could reach about 45 mph on level ground, if given enough time. The PCC also was quiet. It rode on trucks with rubber inserts to reduce noise. Rubber pads even separated the steel wheel treads from the centers. The car was streamlined, as well, and looked as modern as the latest autos. Finally, the motorman could operate the car entirely with foot pedals, leaving his or her hands free to act as a fare cashier. The industry intended to operate the PCC with a crew of one. Passengers would enter one half of a double width front door, filing past the driver to pay fares. They could exit from the other half of the front door or from a double width center or rear door [8, 13].

Improved Transit Bus Technology and Its Replacement of Streetcars

Contributing to blunting the PCC's promise for saving American streetcars were major improvements to bus technology. At the end of the 1920s, bus manufacturers adopted monocoque construction that integrated body and chassis construction into a high-capacity, strong, and lightweight vehicle. Monocoque buses could carry large passenger loads reliably and in comfort by the end of the 1920s. In 1930, such buses began operating every 3 min through the new road tunnel connecting Detroit and Windsor, demonstrating that buses could accommodate mass passenger movements. By 1940, the Yellow Coach Division of General Motors had married the monocoque bus with a lightweight, two-stroke diesel engine connected to the rear wheels via a hydraulic transmission. The result was a transit vehicle that, according to technological historian Robert Post could perform almost as well as the PCC car at comparable operating cost without the need for tracks or electrical overhead wires [8]. The bus had another major advantage, as well. It did not get trapped behind queues of left-turning autos and trucks at busy intersections, increasingly the bane of streetcar operations.

The transit diesel hydraulic bus did have several major disadvantages. Post cites choking diesel exhaust as one. A second was the roar of accelerating diesel engines [8]. Both exhaust and noise were particularly objectionable on more heavily patronized lines with frequent service, and they were severe nuisances in areas of heavy pedestrian activity and confined spaces, such as found in some downtowns. Although diesel buses are far less polluting and much less noisy today, pollution and noise emanating from them remain issues and have led to the reduction of their use through downtowns in Denver and Minneapolis and perhaps other cities [14]. Hilly terrain also intensifies noise and pollution problems and slows heavily loaded diesel buses to a crawl. Another problem was the fact that bus drivers had to use their hands on the steering wheel and thus could not complete dealing with passengers paying fares as the vehicle accelerated, as they often did on PCC streetcars. Diesel buses also had narrow doors, slowing boarding and alighting of heavy passenger volumes.

By the mid-1930s, there was another bus technology that performed about as well as PCC-equipped streetcar lines but avoided air and noise pollution of diesel buses. This was the electric trolley bus. Like the PCC, trolley buses could accelerate rapidly with full passenger loads, but unlike diesel buses trolley buses could zoom quietly up and down steep hills with full passenger loads. Trolley buses took their power from dual overhead wires and could maneuver into lanes right or left of the traffic lane over which the dual wires were strung. Trolley buses did not require tracks, thus saving a large investment, and while they did require overhead electrical wires, they could use most of the same electrical investment that already was in place for streetcars [8].

With the availability of these two bus technologies, the transit industry in America and Canada began the full-scale replacement of streetcars on the eve of World War II [8]. Most American transit systems still were privately operated and, ignoring pollution issues replaced streetcars mostly with diesel buses. There were exceptions, particularly San Francisco and Seattle. These two cities had hilly terrain and municipally operated transit and electric power systems and replaced most streetcars (all in the case of Seattle) with trolley bus systems. Canadian transit systems, most of which were municipally rather than privately operated, were more likely to turn to trolley buses. Most transit systems that installed trolley buses later replaced trolley buses with diesel buses, however. Today, only two cities

in Canada and the USA continue to operate large trolley bus systems: Vancouver, B.C. and San Francisco. Smaller systems remain in Seattle, Dayton, Philadelphia, and Boston.

By the end of the 1960s, vestigial streetcar services remained in only a handful of US cities, and streetcar patronage all but disappeared (Fig. 3). Most of the remaining street car services were operated with PCCs, and most had elements of right-of-way Types B or A, giving the streetcars a speed advantage over buses. Toronto remained the sole city in Canada and the USA that continued to operate a large and heavily patronized streetcar systems mostly with right-of-way Type C. The director of planning for the Toronto Transit Commission during the early 1970s, Robert Topp at that time told one of the authors of this entry that the TTC retained streetcars on heavily patronized routes because in that environment PCCs cost less to operate and provided faster service than buses. Philadelphia also had several streetcar lines still running almost entirely in mixed traffic, but the transit system there converted those to bus operation during the 1980s and 1990s. San Francisco operated one streetcar line primarily in mixed traffic.

Light Rail Transit, Systemic Viability. Figure 3
Between 1930 and 1970 streetcar passengers almost disappeared. Local bus passengers declined dramatically between 1950 and 1970. Only rapid transit passengers (Type A right-of-way) maintained itself against the onslaught of the automobile [15]

The General Motors Conspiracy Explanation for Streetcar Decline

Whether streetcar loss was inevitable is hotly debated. This history shows that the traction industry ceased influencing the growth pattern of US cities between roughly 1915 and 1925 as the auto became the primary mode of urban transportation. The traction industry became unprofitable during this period, and it began losing passengers at an increasing rate as the 1920s progressed. As a consequence, the industry had difficulty financing track and car renewal. The Great Depression accelerated patronage and financing difficulties. Congress further compounded the financing crisis during the mid-1930s by requiring those private electric utility companies that owned transit systems to divest themselves of the transit systems, thus ending a source of cross-subsidy from utility customers to transit users. This action deprived the transit industry of yet another source of capital for renewing itself. All of these developments, in the context of improved bus designs, are enough to explain the near disappearance of streetcars in Canada and the USA by 1970.

Despite the weight of such evidence, popular American culture views the elimination of streetcars as the result of a conspiracy. The role of General Motors in particular in financing conversions of transit services from streetcars to diesel buses formed the basis of Bradford Snell's widely cited 1974 brief [16] arguing that GM orchestrated the decline of rail transit in America to increase the size of a stagnant auto market. Snell was a staff member of the Senate Judiciary Committee. Research by some academics support the Snell thesis [17, 18], and it has entered the popular culture in outlets such as a popular Spielberg movie *Who Framed Roger Rabbit* (1988) and a widely aired Public Broadcasting System documentary *Taken for a Ride* (1996). Informed rebuttals to the Snell thesis, such as Adler's [19] analysis showing that politics between suburban and downtown real estate interests had a lot to do with transit technology decisions, Bianco's critique [20], Post's [8] and Black's [21] analyses have done little to dispel the GM conspiracy theory of streetcar elimination.

It is a fact that General Motors and other automotive interests financed a holding company in the 1930s, called National City Lines, to purchase transit

operating companies around the country. The purpose was to scrap streetcar systems and replace them with buses built by the General Motors subsidiary, Yellow Coach. From then into the 1950s National City Lines purchased streetcar and bus transit systems, and it continued to operate many of its holdings into the 1960s. NCL eliminated streetcar and electric trolley bus service on most but not all of the systems that it purchased. It also outfitted its systems with new Yellow Coach buses [8, 21]. National City Lines pared management of the companies that it took over to the bone but provided staff management services for its operating properties. It also provided financing for new buses and garages, as well. During this period, independent transit companies, because of their unprofitability, had great difficulty financing new streetcar purchases and track and electrical system renewals. National City Lines supporters point to these facts and state that NCL injected desperately needed capital into the transit industry, improved the efficiency of its management, and kept it going in private hands for another couple of decades [15].

In this debate, the authors' side with Post [8] and Black [21] who view, National City Lines as a symptom rather than a cause of streetcar decline. Many private streetcar companies in the USA were not taken over by National City Lines, but they replaced their streetcars with buses despite that fact. In some US cities, such as Los Angeles and Pittsburgh, public agencies took over private rail transit lines (including some from National City Lines) and scrapped their newly acquired rail systems in favor of new buses. It also is true that most Canadian transit systems were municipally owned, but save for Toronto, all converted from streetcar to bus or electric trolley bus. Most cities in France and England eliminated streetcars just before and after World War II, and most cities in Spain did so in the 1950s and 1960s. None of these conversions were the result of US automobile interests.

In the authors' opinion, the US national interest would have been served by modernizing parts of many US streetcar systems at the end of the 1920s by segregating them from auto traffic, but doing so would have required municipalization and capital infusion from higher levels of government. Neither municipalization nor capital infusion from higher levels of government were even remotely in the cards at that time. Even if they had been, given Canada's experience, and experience with public authorities in Los Angeles and Pittsburgh, it is uncertain whether streetcars would have been modernized in the USA. It is safe to say, however, that in the absence of such government takeover and capital infusion, the American streetcar industry could not have maintained itself in private hands because of its unprofitability and inability to raise capital. If National City Lines had not happened, some other combination of liquidators probably would have.

The American and Canadian PCC streetcar operating in motor vehicle traffic almost disappeared because it offered insufficient advantages over the diesel bus to compensate for the expense of its infrastructure, including track and electrical systems. As Post points out, its strongest suit was quietness and absence of fumes. Operationally, it was marginally faster than buses in heavy patronage conditions, at least on roads where left turns were banned, as in some intersections in Toronto (Fig. 2). According to Toronto officials, PCCs carried passengers at less operating cost than buses under the heavy patronage conditions of that city, but other studies showed that it carried passengers at greater operating expense than diesel buses, perhaps because patronage levels were lower in the cases studied [21]. In any event, if there was a case to be made for the PCC streetcar operating in mixed motor vehicle traffic, it was not a strong enough one, and that primarily is why it almost disappeared in North America.

The Light Rail Revolution

Light rail resulted by tweaking the streetcar concept to reduce its drawbacks while enhancing its advantages. The Canadian and American transit industry itself initiated a few of the tweaks, but the industry initiatives came too late in the decline of the Canadian and American streetcar industry to change the trajectory of decline. The progressive changes that did change trajectory came from Europe and crossed the Atlantic in response to the social protest movement in Canada and the USA that began in the 1960s. Many in the American transit industry, who came directly or indirectly from the National City Lines mold, resisted the European ideas but ultimately some were forced to accept them by outside pressure.

In the USA, most of the few streetcar lines that lasted into the 1970s possessed significant elements of right-of-way Types B and A that gave them speed advantages over buses. The speed advantage is why they remained. Five streetcar lines remained in San Francisco; four of them used long tunnels (one 2.5 miles long, the other 1 mile long) that took the lines from the edge of the central business area to suburbs that were cut off by a steep range of hills. Boston had a central streetcar subway that ran outward from its business center, and several streetcar lines fanned out from it like fingers on a hand. The fingers surfaced on ramps, and then ran through inner suburbs in mixed traffic or on reservations in the center of boulevards. Boston ran its PCC cars in one or two car trains, with drivers in both cars collecting fares. In addition to three or four remaining traditional streetcars that ran almost entirely on narrow streets, Philadelphia still operated remnants of three distinct streetcar systems. It had a similar configuration of subway-surface streetcar lines to that of Boston. Philadelphia also continued to operate three or four traditional long streetcar lines running on narrow streets. Finally, it operated two suburban streetcar lines that fanned out from the end of a rapid transit line into the suburbs largely on rights-of-way Type B. Pittsburgh still had one set of streetcar lines that ran south from its business area, which the lines exited through a long tunnel under a range of hills to get to the southern suburbs. All that remained of streetcars in New Jersey was a short streetcar subway in Newark in which individual PCC cars shuttled back and forth between several stations, crossing but not operating in city streets. In Cleveland two streetcar lines ran on reservations in the centers of boulevards in the community of Shaker Heights. The community's developers in 1920 placed expensive homes so that residents had short, pleasant walks to streetcar stops. The two streetcar lines came together into one and then turned onto a railroad corridor that the streetcar tracks followed with Type A right-of-way to a terminal on the edge of the Cleveland CBD, 6 or 7 miles away. Short trains of PCC cars operated on this commuter line at fast speeds.

Some transit advocates argued that rather than representing the dying gasp of an old technology, the surviving streetcar operations with their rights-of-way Types B and A offered a model of a new mode of transit needed in American cities. Bill Adams, an employee of the Boston redevelopment authority and later the Boston transit system wrote a thoughtful article in 1965 describing how the Boston streetcars could be altered to improve their speed and productivity. He was not aware of the light rail transformation then happening in Germany, but what he advocated was very much like what was happening there [22]. Boston did make a much noticed improvement to its streetcar system in 1959 by punching an additional ramp out of its subway and connecting it to a commuter rail line that just had been abandoned, and which then was converted to streetcar operation. The Boston transit system rebuilt the commuter tracks so they were suitable for streetcars, electrified them, and then it began operating frequent service with two- and three-car PCC trains from the outer terminal at Riverside to central Boston via the streetcar subway [8]. An attendant in each car collected fares. Patronage settled down to about 25,000 per day, much greater than what the commuter trains attracted, and Adams and others felt the Riverside line could be a national model. This model led to no emulation, however, except in 1964 for a short shuttle line in the suburbs of Chicago (on right-of-way Type A, part of an abandoned interurban line) called the Skokie Swift [8].

The impetus for the light rail revolution was the social protest movement of the 1960s and the availability of capital from higher levels of government [5, 6]. Continuously falling demand for transit, particularly for bus service, and rising costs forced the US transit industry into an unprofitable position. Between the late 1960s and early 1970s, almost all public transportation in the USA was municipalized with federal and in some cases, state financial assistance. The passage of federal transit legislation in 1970 also made capital available for building new rail systems [11, 23]. At the same time citizen movements, such as those dedicated to preserving neighborhoods by stopping inner city freeways and others to reducing air pollution, came together in some metropolitan areas with the idea that better public transportation systems could help with urban preservation and revitalization [24]. Rail service was clearly desirable, but there was little in the way of immediate domestic examples that seemed relevant to the needs. It was apparent from transit patronage trends (Fig. 3) that bus and streetcar service was in decline, while rail

rapid transit was holding its own against the automobile. Could surface rail systems be tweaked to perform like rapid transit while costing much less to build? If the answer was "yes," there was hope that introduction of such surface rail lines could reverse the declining fortunes of transit and perhaps contribute to renewal of central cities. Thus was born the light rail movement. Its model was not the American streetcar, even the PCC car, but a new concept coming out of northern European cities.

Public transit in most German cities was centered on streetcar technology before and during World War II. As in the USA and Canada, German streetcars ran on tracks located in the middle of streets. The typical German streetcar was a much shorter vehicle than its North American counterpart, however, and German transit providers typically ran them in two- and three-car trains. The first car was a motor car, staffed with a motorman and a conductor. The motor car pulled one or two small trailers, each with a conductor, so the typical German streetcar train of three diminutive cars had a staff of four. The passenger (based on the capacity of the cars)-to-staff ratio was 45:1 [25].

When faced with rebuilding their war-ravaged cities after World War II, German transit planners contemplated a future urban world dominated by the automobile [26]. Should their streetcar systems be rebuilt? Modern buses promised passenger-to-staff ratios of 60:1 for a regular bus and 75:1 for articulated buses, and German transit systems probably would have made the transition to buses at that time had they been able to obtain buses. They were unable to obtain buses, however, and so they put their streetcar systems back together as best as they could. Rapidly rising wages, however, forced German transit operators to seek ways of improving streetcar productivity. In the mid-1950s, they began obtaining larger vehicles, similar in size to PCCs, and then they experimented with articulating two of the large vehicles together into a long-bendable vehicle. The experiments worked. Transit operators improved productivity further by running large trailers behind the articulated cars. They added third sections to the articulated cars. They introduced proof-of-payment (POP) fare systems. POP fare systems required passengers who did not have weekly or monthly passes to figure out what fares they owed and purchase tickets from simple vending machines or tobacco kiosks before boarding vehicles. No staff would inspect their fare upon boarding, but roving bands of inspectors could ask them to produce proof of payment at any time during their journeys, and if they failed to produce adequate proof, they could be fined. This system added teams of roving inspectors to the payroll, but it eventually eliminated all conductors on all cars. Passenger-to-staff ratios rose to over 200 [25]. The increase in streetcar productivity was so large that many transport undertakings decided to retain streetcars but adapt them to conditions where it was expected that most of the public would use automobiles in the future [26]. A British publication *Modern Tramway* reported regularly on the transition of the streetcar systems in many northern European cities into what later became known in North America as light rail.

Figure 2 offers a vantage point for understanding what the German's were trying to do with their streetcar technology makeover, as evidenced from the pages of *Modern Tramway*. Figure 2 shows a two-car PCC train on the Queen Street line in central Toronto that was given some priority over autos. Both the operation of a second car as well as auto priority were significant improvements over traditional North American streetcar practice and undoubtedly contributed to the higher performance of the Toronto streetcars in handling high passenger volumes compared to buses. Would it not be possible to take such modifications further? Could three-car trains be operated? Could drivers on the second and third cars be eliminated to improve productivity? Could the fare collection system be changed so that passengers could board at all doors on the train, without being impeded by an employee collecting fares and transfer slips? Could motorists be kept off the tracks? Could all left turn conflicts be avoided? Could the service be speeded up by stretching out the distance between stations, and could the stations be designed to be safe from auto traffic and integrated with pedestrian systems, with easy transfers between bus and rail? Could the entire bus route structure in the region be changed to dump the heaviest passenger loads onto streetcar routes experiencing such modification, taking advantage of their speed and high passenger carrying capacity, leaving local diesel buses to handle lighter loads? In short, rather than having the streetcar act

like a slow local bus on rails, could it act more like a quiet fast subway train operating on the surface (perhaps dipping into short subways in the heart of the CBD), becoming the backbone to a regional transit system? The answer to all of these questions was, and is, "Yes," and German transit thinkers (as well as transit thinkers in Switzerland, the Netherlands, Belgium, and Sweden) developed technology and operating procedures for doing it. Getting transit systems in the USA and Canada to adopt and implement such technology and procedures was what the light rail revolution was all about.

In a major study that took place about 1959, Frankfurt am Main in West Germany compared different strategies for region-wide public transport improvements. One was based on building a system of subway lines fed by buses. The other was a system of light rail trains running in short subways in the center of the city and then using Type B rights-of-way everywhere else. Frankfurt decided in 1960 to follow the second path [27, 28]. Figures 4–7 offer several glimpses of the evolution of the Frankfurt streetcar system to a light rail network. Similar modifications were happening to streetcar systems in cities throughout northern Europe at this time [29].

The German concept of light rail entered North America through different channels. *Modern Tramways* was an important conduit, prompting at least two US consultants to visit Germany to see for themselves and then write about their observations in *Traffic Quarterly*. In 1962, Dean Quinby, a consultant working on the BART project in the Bay Area, captured the essence of the idea, which was more than just separating streetcars from autos. It was the idea of creating surface, or *light infrastructure* rapid transit that could be afforded by midsized cities. Door design and efficient fare collection design were important parts of the concept [30]. Eight years later, Stuart Taylor captured the momentum of the idea that was spreading across northern Europe and again argued that the idea had great applicability to the USA [31].

Other readers of *Modern Tramways* included Senator James R. Mills, president pro tempore of the California State Senate, who brought light rail to San Diego in 1981, the first application in the USA. Mills' most vehement opponent in introducing light rail was San Diego Transit's general manager, who also was president of the American Public Transit Association. San Diego's MPO, the Comprehensive Planning Organization, who sought a Washington Metro-like regional

rapid transit system, also opposed light rail, but both San Diego Transit and CPO lost the battle [32].

Readers of *Modern Tramways* also included Tom Parkinson, a British electrical engineer, who introduced the self service, barrier free fare (proof-of-payment or POP) fare system, so critical to the success of light rail, to North America. Parkinson installed POP on Seabus in Vancouver (1978), then on the new light rail line in

Light Rail Transit, Systemic Viability. Figure 7

Edmonton (1978), and then on the San Diego Trolley (1981). With the proof-of-payment fare system, passengers bought passes allowing from 90 min of riding to a month of riding at vending machines on platforms or at retail outlets. Passengers were required while on board trains to have in their possession a valid ticket or pass, inspected at random by roving teams of fare inspectors. This system eliminated the need for drivers to inspect fares and allowed passengers to board through all doors, making it possible for several hundred passengers to board in a matter of seconds [32]. Parkinson, with Walter Quintin of Bechtel, also wrote the car specs for the first San Diego line. Only six pages long, the spec was a stunning contrast to the phonebook sized spec that the Urban Mass Transit Administration issued for the flawed standard light rail vehicle, which ultimately was ordered only by San Francisco and Boston. The Parkinson/Quintin spec led to San Diego selecting the DueWag U2 car (Fig. 7) [32]. The U2 was a rugged, reliable and easily maintained car originally introduced in Frankfurt in 1968 and already selected by Edmonton and Calgary for their light rail lines. In addition to its use in San Diego, updated versions of the U2 car would be used later by Sacramento, Pittsburgh, and other operators, and it became the de facto standard light rail vehicle in North America [8].

The light rail idea also was brought into the USA by academics and high government officials who lived in Europe during this period and then moved to or back to the USA. Such persons included Professors Vukan Vuchic of the University of Pennsylvania, who published a summary of European light rail practice on behalf of the new Urban Mass Transit Administration. Another notable member of this initial group was Professor John Bakker, a civil engineering professor at the University of Alberta who worked closely with Don MacDonald, the Superintendent of the Edmonton Transit System to define a short rail system around which a timed transfer bus system (based on ideas from the Netherlands) could be structured. Edmonton would be the first modern light rail adoption in North America. The group included Bob Burco, who headed the Oregon Department of Transportation when light rail was adopted in Portland, and Ken Orski, who as Deputy Administrator of UMTA wrote a policy directing MPOs to consider light rail among alternatives for transportation improvement in their long-range transportation plans. Vuchic, Stuart Taylor, and Orski worked together to establish what became known

as the Light Rail Subcommittee of the Transportation Research Board's Rail Transit Committee in 1974. Shortly after its formation, the subcommittee branded the German concept of limited tramways as light rail, and held a national conference on light rail in June 1975 to popularize the idea among politicians, regional planning officials, and transit managers in cities in the USA and Canada. Leadership of the American Public Transit Association joined as a cosponsor of the conference at the last minute, though many in leadership positions then were opposed to the idea of light rail [5, 6].

A characteristic of German light rail that differed from American streetcars was the German practice of imbedding light rail lines into regional transit networks. The coordination of light rail and bus routes, as it came to be practiced in North America, was done to accomplish two objectives. One was to take advantage of the high passenger-to-staff ratios of light rail lines to improve overall transit productivity. The idea here was to introduce light rail lines into corridors served by many bus lines, particularly during rush hours. Rather than operating all of the bus routes to the CBD on arterial roads, where there were large amounts of redundant bus service, the transit operator would terminate bus routes at suburban light rail stations. High-capacity light rail trains then could take passengers to the CBD, and perhaps to other important destinations that bus passengers previously could not reach. Staff and operating expense would be saved by discontinuing the duplicative parts of the bus routes running from the suburban stations to the CBD.

The other objective of bus and light rail service coordination was the creation of multidestination transit networks that enabled those passengers without access to autos to reach many metropolitan area destinations in addition to the CBD. Suburban light rail stations where many bus routes converged were excellent places for passengers to transfer not only between buses and trains, but also between trains and buses (so that train passengers could reach nearby destinations), and between one suburban bus line and another.

Ideas of bus/rail coordination to achieve the dual objectives of greater productivity and multidestination travel were new to transit systems in the USA. US transit planners typically viewed the CBD as the only important destination for transit to serve. They believed that to attract as many passengers as possible to the CBD, it was important not to force passengers to transfer from buses to trains [39]. American (but not necessarily Canadian) practice tended to view each transit line as an independent entity that connected suburban neighborhoods with the CBD.

The idea of multidestination transit came into Canada and the USA from several directions. John Bakker and Don MacDonald of Edmonton saw light rail as the core of a restructured city-wide bus network much as they saw happening in Europe. Brian Sullivan of Edmonton, Calgary, and Vancouver also realized the importance of bus rail service integration for both reducing costs and increasing patronage. Sullivan passionately argued for the network approach and attempted to import the German idea of the *Verkehrsverbund*, or traffic federation, to North America. The idea of the *Verkehrsverbund*, pioneered in Hamburg, was that a central planning and marketing agency in an urban region would design a regional transit network to allow easy travel throughout the region by transfers between lines and modes. The traffic union would establish timetables, collect fare revenue, and provide information to the public for all transit services in the urban region. However, it would contract out the construction and operation of different parts of the network to many different entities. From the public's perspective, the entire regional network would seem to be one coordinated entity. There would be only one regional transit map, one source of timetables, and one fare system. The public would be able to transfer freely between all parts of the system, connections would be timed, and transfer stations would be attractive and functional. However, different operators would be able to keep close managerial control over the independent parts of the network, insuring timely operation and low operating costs. Sullivan, Bakker, and MacDonald had considerable success in spreading at least parts of these ideas either directly or through coworkers (such as Tom Matoff and Greg Thompson) to Vancouver, San Diego, Edmonton, Calgary, Portland, Sacramento, and Denver. Under the leadership of Tom Larwin, MTDB's general manager from 1978 to 2003, San Diego was the one region in the USA and Canada that came closest to implementing the *Vehrkehrsverbund*, where the concept was the organizing principle for regional transit in the southern part of San Diego County from 1979 to 2003 [32].

Vancouver also adopted many aspects of the traffic union concept through British Columbia's Bureau of Transit Services. Sullivan, who was deputy director of the province's Bureau of Transit Services from 1973 to 1980, led a team in preparing a transit plan for the region calling for the region's extensive local bus and trolley bus system to be reorganized around a core of regional light rail lines and regional buses, called Fast Buses. The plan largely has been implemented, though the region obtained the funding to build its rail lines as entirely Type A rapid transit lines rather than as light rail. Other regions, such as Denver, also adopted the concept of an integrated regional network but attempt to manage the concept through large public monopolies.

Also important to the transference of the light rail idea from northern Europe to North America was the mass travel of Canadian and US youth to Europe during this period [24]. By and large, these travelers were the offspring of middle class families who grew up in the suburbs using automobiles. In Europe, however, they rode between great urban centers on fast, comfortable, frequent trains on first-class Eurail passes and used the modernizing tram systems in cities throughout northern Europe. Many came back with the realization that there was a viable urban alternative to suburban, auto-based neighborhoods that they experienced as kids. Such individuals, passionate in their beliefs, entered transportation bureaucracies in Edmonton, Vancouver, San Diego, Portland, San Francisco, Sacramento, among other cities in the late 1960s and 1970s, and worked with other such individuals in citizen activist groups to get the light rail idea accepted by top decision makers [24].

Light Rail Adoption in North America

Table 1 summarizes the history of light rail adoption in Canada and the USA as well as the streetcar systems that survived to 1970 and then were modernized. The table shows the year that a previously all-bus urban area opened its first light rail line and the miles of line that it originally opened. The table also indicates growth, if any, from the original length, and the passengers boarding the light rail lines each weekday in a recent year (generally 2006). Some systems cater to passengers who travel only a short distance; others to passengers who travel a long distance. Average distance traveled for each city is shown, as is the speed of service. The next to last column shows the current (usually 2006) traffic density on each mile of line. Density is measured by the average number of passengers passing each mile of line on a typical weekday. The primary purpose of showing the relative traffic intensity of the various systems is to offer a first cut to judging their relative performance.

This section summarizes how the first group of North American bus-only cities to adopt light rail decided how to do so. There are seven such cities. The section shows a great deal of commonalty of objectives among five of the seven pioneer cities, and understanding the commonality assists in evaluating the success of the light rail movement in the section of this entry that follows. This section stops at the first seven because there is a clear gap between the seventh and eighth city in terms of time, after which the rate of adoption increased rapidly.

Edmonton was first. During the 1950s, 1960s, and 1970s, a city department, the Edmonton Transit System operated the area's bus and trolley bus system under the direction of an electrical engineer, Don MacDonald. MacDonald began his career with Edmonton Transit by replacing the system's streetcars with trolley buses just after World War II, when he was made Superintendant. During the 1960s MacDonald collaborated with a Dutch university transit engineering professor, John Bakker, in forming strategy for system change. MacDonald and Bakker developed a plan for a short Type A rail transit line using railroad rights-of-way modeled roughly after a similar line that opened in Cleveland in1955. In contrast to Cleveland where the rail investment resulted in no significant changes to the city's bus system, MacDonald and Bakker intended to restructure the Edmonton bus and trolley bus network around the rail line, eliminating duplication of trunk bus routes running to the CBD, and making suburban destinations more reachable. They could not obtain funding or council approval for the project, however. This changed about 1970 when two university-affiliated activist groups organized to fight city hall's effort to bulldoze inner city neighborhoods, nature corridors, and parks to make way for an inner city freeway ring. Their 1971 book addressed to Edmonton's city council, "Immorality of the Motor

Car," persuaded City Council to scrap the previously secret freeway plan for the city. A year later, the activists presented City Council with a second book, "Light Rapid Transit, the (Immediate) Answer for Edmonton." This book, with a line drawing of the 1968 Frankfurt U2 car on the cover and heavily footnoted with references from *Modern Tramway* and *Traffic Quarterly*, presented the light rail idea. The principal authors had been acquainted with light rail on European trips. "Light Rapid Transit . . . ," then described how the idea could be applied to Edmonton, including diagrams showing how bus routes could be restructured around suburban light rail stations (Fig. 8). Oil royalties then flowing into provincial coffers led to a provincial light rail construction fund available to both Edmonton and Calgary, and Edmonton City Council approved light rail development in 1973. Edmonton opened its first line with turnstiles but

Light Rail Transit, Systemic Viability. Figure 8
Neighborhood activist vision for an integrated bus and light rail network for Edmonton in 1972. Taken from the Practicum on Community Analysis, "Light rapid transit: the (immediate) answer for Edmonton"

within a year replaced them with the proof-of-payment (POP) fare collection system after its successful debut for Vancouver's Seabus. The POP fare collection system made it easier for passengers to transfer between buses and trains, and station designs generally required short walks between modes. Edmonton made the mistake of putting the CBD part of its light rail line in a subway, however, which greatly increased light rail construction cost, thus slowing light rail expansion. Not until 2003 did the line finally break to the surface on its southern face. Since then, it has expanded to the south rapidly, and its patronage more than doubled since 2003 as a consequence [5, 6].

Edmonton's light rail system still lags the light rail impact of Calgary, however. Under the direction of William Kuyt, a Belgian-born traffic engineer who already was familiar with light rail, Calgary put its light rail line comingled with buses on a surface mall through the CBD. With the same amount of money that Edmonton received from the provincial government, Calgary subsequently expanded more rapidly and farther in several directions in the manner described in, "Light Rapid Transit…". The Calgary light rail line directly serves most of the metropolitan area's major destinations, and Kuyt restructured its bus system around its three lines in the manner projected for Edmonton in Fig. 8.

San Diego was the first US urban area to open light rail, and it followed the example of Edmonton (though it avoided subway construction). San Diego's light rail was championed by the President Pro Tempore of the California State Senate, James R. Mills of San Diego. Opponents included the city-owned and federally financed bus system and the federally sanctioned metropolitan planning organization, called the Comprehensive Planning Organization. The bus system's general manager maintained that buses could do anything a rail system could do better and at lower cost. The MPO viewed light rail as interfering with its plans for a Washington Metro-like system. Arguing that the bus system already exhausted the region's financial resources for transit with unproductive bus service and that the MPO's plans were financially and politically infeasible, Senator Mills put forward the German concept of light rail as a feasible alternative to both. An avid reader of *Modern Tramways*, he persuaded the San Diego County Department of Transportation to study the feasibility of the German light rail concept in San Diego. The department's head, Rudy Massman hired an engineer and a planner from the Edmonton Transit System during a window when it looked like political approval for the Edmonton system would not happen. Massmann married the Edmonton transit people with San Diego County roadway department project planning and financing staff to prepare the study. The study found that a regional network of light rail trunk lines, around which bus service in the county was restructured, was a viable transit concept for the highly decentralized and auto-centric San Diego region. On the basis of the report, the Senator carried legislation that stripped the city bus system and the MPO of much of their powers, created a new transit planning, programming, and construction organization (the San Diego Metropolitan Transit Development Board, or MTDB), and gave it access to state and local funding. The legislation creating MTDB envisioned light rail becoming the backbone of a regional transit system, and it gave MTDB the power to make that happen. The first MTDB general manager, Robert Nelson sold the MTDB to business leaders in the region by arguing that light rail was the only way to improve transit productivity in the region by replacing a large number of unproductive bus miles with productive rail miles. Earlier as Deputy General Manager for the Metropolitan Atlanta Transit Authority, Nelson made similar arguments there. With such arguments, MTDB gained local support for its plans, and when Mayor Pete Wilson of San Diego swung on board, the project moved forward. From the opening day, the San Diego Trolley used the POP fare collection systems, and as the LRT network expanded, bus routes have been restructured around light rail stations. The *Verkehrsverbund* form or organization, described earlier, governed the region for over 20 years of light rail expansion [14, 32].

As Edmonton's, but unlike San Diego's, Portland's light rail decision grew out of pro-neighborhood and anti-freeway organizations that coalesced in that city during the early 1970s. The region used Interstate Transfer Funds freed up by a deleted freeway to finance part of the light rail line. As in San Diego, the concept of light rail development in Portland was heavily influenced by Edmonton and incorporated Canadian ideas of light rail forming the armature of a

restructured regional bus system. The first document advocating light rail in Portland was a state Public Utilities Commission examination of the suitability of using rail rights-of-way in the Portland region for rail transit or busways. The author of the document patterned it on, "Light Rapid Transit, the Immediate Answer for Edmonton," which he cited. Most of the major players in the decision to adopt light rail in Portland had been to Europe and seen the concept there. Some were readers of *Modern Tramways*. One of them was the transit system's planner, but the management of the transit system was otherwise opposed to light rail. The governor had to reorganize it, and also change staff at the Oregon Department of Transportation before light rail could move forward. The reorganized transit system (TriMet) took the lead in designing the integrated light rail/bus system. It hired Don MacDonald from Edmonton to manage Portland's first light rail construction as well as to plan for restructuring bus service around proposed light rail trunk lines [24]. The Canadian approach was strengthened in Portland by Tom Matoff, who brought Portland's first light rail line into operation and restructured eastern city and suburban bus lines around it in time for the first day of operation. Matoff had worked with Brian Sullivan in Vancouver on the Vancouver regional rail/bus integration concept and its incorporation into the *Greater Vancouver Regional Plan*. Sullivan brought Matoff to Vancouver, and from Vancouver Matoff moved to San Francisco, where he was director of planning for the San Francisco Municipal Railway. In that capacity, Matoff initiated and secured adoption of a revolutionary plan for restructuring the San Francisco Municipal Railway's bus and trolley bus network around the new light rail transit subway investment in that city. From there, he moved to Portland, San Jose rail operations, and later still to Sacramento.

As did Portland, Sacramento used Interstate Transfer funds to finance part of the construction of its first light rail lines, which also arose out of an anti-freeway, neighborhood revitalization movement. Youthful activists in that movement previously traveled widely in Europe and read *Modern Tramways*. Despite the project's anti-freeway origins, the California Department of Transportation, which had assisted in the San Diego light rail project, contributed significantly to the design of the Sacramento proposal. The bus transit system, run by a regional district, originally was opposed to light rail. However, Bob Nelson, who was the San Diego Metropolitan Transit Development Board's first general manager, and as such led in the design and adoption of San Diego's first light rail line, was appointed general manager of the Sacramento system after leaving San Diego. Nelson was not directly involved in light rail planning in Sacramento, but he and John Schumann, who was (as director of a special agency to plan and construct light rail), sold light rail to the business community there as a means for improving transit productivity by eliminating bus route duplication. Nelson previously used this argument in San Diego (and before that, he used it in Atlanta with its heavy rail system) with success. After opening Portland's light rail system, and a year after Sacramento's first light rail line opened, Tom Matoff became Sacramento Regional Transit's general manager and insured a coordinated light rail/bus system there for its first several years. Unfortunately, more recent extensions have not been supported by bus restructuring, and the old bus people there have dismantled much of the original coordinated rail/bus scheduling from the earlier era [14].

The close linkages between development of five of the pioneer light rail systems result in a commonality of system design between them. In all five cases, light rail was envisioned as the backbone of restructured regional transit systems, and in four of the five cases this idea has been kept as their light rail systems expanded. Four of the five cases now experience high passenger traffic density on their light rail lines, exceeding 10,000 passenger miles per track mile of route. Light rail in Sacramento does not achieve this intensity of use, perhaps because that system's commitment of bus/rail coordination has waned.

Buffalo and San Jose followed different paths to light rail development that resulted in less coordination between their bus systems and light rail lines. Buffalo's light rail line was conceived by the region's transit operator originally as a heavy rail line using Type A right-of-way. The transit authority requested federal and state funding for their project but was turned down. However, the Urban Mass Transit Administration was looking for a light rail demonstration project that it could finance, and it chose Buffalo. To transform

the original proposal from heavy rail to light rail so that it could obtain federal funding, the transit authority redesigned the plans so that rail cars would run for a mile along a transit mall, built on the right-of-way of the downtown's major shopping street. For the remaining 5 miles from the edge of the downtown to a university campus in the northeastern sector of the city, the line ran in a subway, stopping at several underground stations. The cost of the subway made it impossible to extend the line any farther, though a surface extension farther into the suburbs was in the original plans. The line did open with the POP fare systems, and there are unimpeded transfers between bus and rail. However, it does not appear that there was a significant restructuring of the bus network around the light rail investment, even though the same agency in the Buffalo area runs both the bus and light rail lines.

Local business support focused by a political leader, Rod Diridon was the momentum behind light rail development in the San Jose metropolitan area. Diridon held several elected positions but was particularly active as a Santa Clara County supervisor, where he organized a county-wide transit system to develop bus and rail service in the area. With support of the business community leadership, Diridon obtained state funding opportunities for transit made available through the leadership of Senator James Mills of San Diego, and he also obtained federal funding to support light rail plans. The San Jose light rail initiative differed from that in San Diego, however, by not following the transit planning objective of having light rail forming the core of a regional bus system, which was one of the principles around which the legislation creating the MTDB was written. Both light rail and buses now are operated by the same county transit authority in the San Jose area, but the two systems are not well integrated. In many locations, transfers between modes require long walks in pedestrian-hostile environments, and there never was a strategic vision of integrating light rail and bus lines into a regional system in which the heavy investment in light rail would replace the trunk parts of bus routes headed to major destinations. Matoff was brought in to open the first light rail line in San Jose following his successful opening of Portland's first line, but unlike in Portland he was not charged with establishing a coordinated bus and light rail network in San Jose, and there had been no ground work in that direction before he got there. There is another problem, as well. Because of a design flaw of the CBD mall that has proven impervious to correction, the light rail system is plagued with a 10-mph speed restriction through San Jose's CBD, which lengthens travel times between residential districts in the southern part of the county and employment concentrations, which tend to lie north of the CBD [14].

During this period, most of the streetcar lines that survived to 1970s were modernized. All except New Orleans and Toronto received fleets of light rail cars. The Urban Mass Transit Administration wrote specifications for what it intended to be the standard light rail vehicle for the United States, and it encouraged Boston and San Francisco to be the first purchasers of the car. Boeing-Vertol was selected to build it, but the car proved to be complicated and unreliable. No other orders followed. Other systems ordered the U2 car or cars built by different builders but similar to the U2 car. Toronto replaced its PCCs with new vehicles of similar design built in Canada. New Orleans renewed its old pre-PCC traditional streetcars and expanded the fleet with replicas. Changes to the physical plants of the streetcar systems varied widely from city to city. Pittsburgh rebuilt its South Hills lines to light rail standards and placed the CBD part in a new streetcar subway. Cleveland renewed its Shaker Heights lines, which already were mostly on Type B right-of-way. San Francisco placed the CBD portion of its streetcars into a subway, which connects with the two long tunnels extending into the suburbs. The subway was a byproduct of regional rapid transit development. Even with the streetcar subway running beneath Market Street, the city's transit system continues to operate streetcars on tracks in the center of the street as part of an historic streetcar line. In 2007, San Francisco's transit system opened a new light rail line to the southern part of the city using right-of-way Type B. Boston and Philadelphia renewed their already existing subway-surface streetcar lines with Type B right-of-way. Philadelphia made major streetcar cutbacks, however, by eliminating all of its north–south Type C streetcar routes. It since restored one of them using rebuilt PCCs. Route 15 – Girard Avenue intersects both the Broad Street Subway and Market-Frankford Elevated rapid transit lines. Boston also abandoned some Type C

streetcar service. New Orleans renewed its traditional St. Charles Street streetcar operation, and it expanded its streetcar operation by converting its heaviest bus route to streetcar operation. Before Hurricane Katrina temporarily shut the system down in August 2005, the New Orleans streetcar operation remained slow and traditional.

How streetcars function as a part of the overall transit system varies from city to city. Metropolitan Toronto's transit system was one of the few to have been organized as a grid network of north–south and east–west routes from the 1920s. Streetcars serve some of the heavy east–west routes in the grid, and they intersect with north–south bus, subway, and in some cases, other streetcars at every major north–south cross street. The transit system provides many off-street transfer stations that allow passenger to transfer between vehicles, using all doors, without drivers supervising their fare collection [37].

For years, Boston's streetcars have operated as radial routes funneling into the CBD-destined streetcar subway, which intersects with three rapid transit subway lines in the CBD. The streetcar subway then continues out the northern end of the CBD, where it serves a major commuter train terminal before crossing the Charles River and terminating at a streetcar/bus transfer station at Lechmere. Very few bus routes enter Boston's CBD, so almost all bus passengers destined for the CBD transfer to the streetcar subway or the other three rapid transit lines.

During the early 1980s, under the direction of Muni Planning Director Tom Matoff, the San Francisco Municipal Railway extensively restructured bus and trolley bus routes in the central part of the city to better serve non-CBD destinations. The transit system created new crosstown bus routes that intersected with the light rail subway running to the downtown. Parts of the bus routes previously running from the stations to the CBD were discontinued, and passengers heading to the CBD transferred to trains. The change was intended to increase productivity and make more destinations reachable by transit, thus increasing patronage.

In Pittsburgh, Cleveland, and Philadelphia transit service remains organized primarily as radial bus and streetcar (and in the case of Cleveland and Philadelphia, rapid transit lines) operating to the CBD. In some cases, passengers have to pay an additional fare to transfer between routes, and most passengers do not transfer. The subway-surface streetcar lines are not the organizing principle of area-wide route restructuring but function as just other transit routes heading downtown. (However, the 15 – Girard is a crosstown line functioning as part of the North Philadelphia grid system.)

This entry generally does not consider previously all-bus cities that built new streetcar lines during the last two decades. There are several of these. Most of the new streetcar lines are short urban circulator or tourist-oriented loops in central city areas. Table 1 does show one of these streetcars, however, partly because the line is longer than others and functions as a transit line connecting several destinations together. It also is shown, because its statistics had to be disentangled from Portland's light rail statistics in the construction of Table 1.

Analysis of Light Rail Transit Performance

Light rail advocates hoped that their efforts would increase transit use, improve transit productivity, and create North American lifestyles that could be independent of automobiles. There are no comprehensive studies that evaluate the extent to which such objectives have been reached, but there are academic studies that touch on light rail performance. Some are critical of light rail investments for costing a lot while achieving very little, while other studies show that light rail investments have had favorable impacts on transit system performance if the investments were planned to improve transit productivity. This section examines light rail performance. It first considers academic criticisms of light rail investments, followed by examinations of how light rail investments have affected overall transit performance in different metropolitan areas.

The primary conclusion from the various analyses is that light rail investments that have been accompanied by restructuring of bus systems have increased transit riding per capita in their service areas, and they have been more productive and more efficient in this regard than alternative forms of transit investment. Light rail investments accompanied by bus network restructuring have been particularly effective in rapidly growing parts of the country. Light rail investments not

accompanied by bus route restructuring have been less effective. New streetcar investments that eschew light rail productivity enhancements appear to be less effective, as well. Light rail investments have not, however, substituted for auto traffic to a large extent.

Criticisms of Rail Investments

Light rail traffic densities shown in Table 1 suggest that some light rail lines, such as in Salt Lake or Phoenix, are carrying sizable traffic in sprawling, auto-oriented regions where heavy rail transit volumes would not be expected. Examining the patronage consequences of new light rail transit investments throughout the USA, Polzin [38] found that although light rail patronage initially was disappointing, it was growing considerably as various systems expanded in scope. Light rail critics counter, however, that traffic density figures are not an indication of whether light rail investments increased transit ridership or reduced transit costs. They argue that without rail most of the same patronage would occur on buses at lower cost. Some critics argue that patronage actually would be higher without rail. Rail investments and operating expenses, they argue, starves the bus system of funds, resulting in its emaciation and loss of patronage. Without the rail lines, the bus systems would be much healthier and would have more patronage.

Arguments critical of light rail investments stem from the 1966 work of Meyer, Kain, and Wohl [39], which laid out an argument against investing in rail transit. They argued that public transportation was effective in only one market, which was connecting suburbs with CBDs. Unfortunately, CBDs had been in decline for almost a half century, and census data suggested the decline would continue into the foreseeable future. Thus, transit patronage would continue to decline. They also showed that for the suburb to CBD market, under almost all conceivable residential densities in the suburbs and employment densities in the CBD, express buses on freeways were a better choice than rail transit. Express buses could provide faster service with a one-seat ride at lower cost per passenger than rail transit lines. The latter were more expensive to build and operate, they argued, and required passengers to transfer from local buses to rail lines at suburban stations. Even worse, rail transit lines sometimes required a second transfer from rail to bus in the CBD. This type of argument has been used against proposed rail transit investments in numerous cities, and it also is used against restructuring of bus services around rail transit lines. The transit system opponents to light rail in San Diego, for example, appealed to these arguments extensively.

Examining patronage and cost data from recent heavy and light rail investments in the early 1990s, Pickrell [40] argued that rail transit supporters obtained political support for their projects by inflating patronage projections and underestimating cost projections. Kain [41] offered a case study on how such deception was used in Dallas. O'Toole [42] and Richmond [43] also provided empirical evidence showing that the actual costs of rail projects were greater and patronage less than projected. They also claimed that rail investments depressed transit patronage and increased transit costs compared to doing nothing or using similar investments for express buses. Richmond did report that there was one rail investment that improved transit patronage and reduced costs: San Diego.

In a forthcoming article, Giuliano argues that transit investments in the USA fail to achieve their objectives. She argues that the investments are large. In 2006, for example, all levels of government in the USA spent $36 billion for transit capital investments and for subsidizing two-thirds of transit operation expenses for that year. Such large expenditures in that year and in all prior years leading up to 2006 did little to expand transit ridership or influence urban form. She further argues that transit in the USA is useful primarily to the poor, but that government expenditures in transit do little to increase transit's usefulness to the poor. She includes expenditures on light rail development among expenditures that fail to achieve objectives or help the poor [44].

Comparison of Transit Performance in Urban Areas With and Without Light Rail Investments

The criticisms of rail transit investments suggest that metropolitan regions investing in rail transit will have lower overall transit ridership per capita than comparable regions that have bus-only transit systems. While trains might carry substantial patronage, it is suggested

by critics that the overall train plus bus patronage would be lower than the all-bus patronage in a region that did not invest in rail. The criticisms also suggest that the overall transit productivity, measured in passenger miles per vehicle mile, would be lower in urban areas with rail compared to similar regions with only buses. Finally, rail critics imply that the rail plus bus operating expense for moving each passenger 1 mile in urban regions that invested in rail would be higher than the bus-only operating expense for moving each passenger 1 mile in urban regions that did not invest in rail.

Brown and Thompson [45] tested these assertions for US metropolitan areas that contained between 1 and 5 million people. There were 45 of such midsized urban areas. Many light rail new starts were made within this group of metropolitan areas, and other metropolitan areas in this group considered light rail but decided not to implement it, such as Kansas City, Cincinnati, and Columbus. Brown and Thompson divided the 45 metropolitan areas into four categories. The first category contained bus-only metropolitan areas where the transit systems organized bus routes to carry passengers to many destinations. Six metropolitan areas fell into this category (Table 2). The second category contained metropolitan areas that operated both bus and rail routes (light rail in most cases), and the bus and rail routes were organized to reduce duplication of bus routes and to carry passengers to many different destinations. There were 10 metropolitan areas in this category. The third category contained metropolitan areas that operated both bus and rail routes, but most of the routes were radial in nature, focused on the CBD. The fourth, and largest category (20 metropolitan areas), contained metropolitan areas that operated only buses, and the bus routes mostly focused on the CBD.

Having established the categories, Brown and Thompson then calculated median transit performance in 1984 and 2004 for each of the four categories, using three performance measures. One performance measure was annual passenger miles per capita for the region. This measure indicates the degree to which the average inhabitant of the region uses transit. Another performance measures was passenger miles per vehicle mile, which indicates the average number of passengers on board a transit vehicle each mile that it operates. This is a measure of productivity. The remaining performance measure is total transit operating expense per passenger mile, expressed in real dollars that remove inflation. This is a measure of operating efficiency.

Tables 3–5 show the results. The multidestination bus plus rail category outperforms the other three categories by a wide margin. This is the category that includes cities that invested in light rail and reconfigured the bus route structure around new rail lines (San Diego, Portland, Atlanta, Miami, St. Louis as examples). Most of the rail transit investments were light rail, though Atlanta's and Miami's rail investments were rapid transit lines. This is the only category to increase transit patronage per capita (Table 3). It is the category to have the lowest reduction in transit productivity, and three of the light rail/bus systems actually increased their productivity (Portland, St. Louis, San Diego). It also is the category to have the lowest increase in operating costs. By 2004, operating costs in this category were far lower than in the radial bus-only category.

The multidestination bus and rail category performed well despite poor performance of two of its metropolitan areas: Sacramento and New Orleans. As noted earlier, Sacramento partially abandoned coordination between buses and trains that characterized the system in its early years. New Orleans saw the worst change in performance on all three performance indicators. Slow traditional streetcar lines do not appear to be good for transit performance.

Urban areas that invested in rail but operated most of their rail and bus routes to the CBD did not do well. Such urban areas include Pittsburgh, Cleveland, and Buffalo. These metropolitan areas saw declines in most of the performance indicators. Salt Lake and Memphis, however, did well. Memphis is included in the rail category because it invested in a short downtown circulator streetcar. Carrying about 3,400 passengers per day, the Memphis streetcar carries about 10% of transit patronage in the Memphis metropolitan area [36]. Salt Lake operates a long, fast light rail line with a short branch to a university. The two light rail lines serve several important destinations, while the bus system was very sparsely developed before the light rail line was built and changed little with its opening.

The worst-performing category for each performance measure is the radial all-bus category, which is

Light Rail Transit, Systemic Viability. Table 2 Classification of 45 midsized US metropolitan areas into four categories based on mode of transit and orientation of route structure

Providence	29.31%		

the category that contains almost half of the transit systems. In 2004, the median metropolitan area in this category had only one-fifth the transit ridership per capita as the median multidestination bus-rail system (Table 3). Over the preceding 20 years, the median decline in ridership per capita for the all-bus radial category was 13%, while the median increase in ridership per capita for the multidestination bus/rail category was 9% (Table 3). Productivity for the median all-bus radial category was about a third worse (Table 4),

while operating expenses per passenger mile were about a third more than the median for the bus/rail multidestination category (Table 5). Real operating expenses per passenger mile for the median all-bus radial category also increased almost four times faster than real operating expenses per passenger mile for the median multidestination rail/bus system (Table 5). Most if not all of the metropolitan areas in this category invested very little in their bus systems for busways. Over the 20 years of the study, they also tended not to expand bus miles to provide more coverage or greater frequency. In short, there is little evidence that because they did not invest in rail transit that they improved their bus systems instead.

Overall, the results of Brown and Thompson [45] suggest that light rail investments around which bus services are reconfigured into multidestination transit systems increase their ridership more, have greater ridership, have greater productivity, and cost less to operate than all-bus systems and rail plus bus systems that focus most of their routes on CBDs. These results appear to occur, because travel markets are more complex than the simple suburb to CBD model originally postulated by Meyer, Kain, and Wohl in 1966. Residents in metropolitan areas are traveling to multitudes of different destinations in addition to CBDs. The multidestination bus/rail systems appear to be better suited to tapping the more complex travel markets than the radial all-bus and bus/rail transit systems. Another study confirmed this point. It shows that regional employment reachable by bus and train combinations in Atlanta is important for explaining rail ridership on Atlanta's rapid transit lines. Fluctuations of employment in Atlanta's CBD are not important, primarily because CBD employment is such a small part of employment in the rest of the transit system's service area. Employment outside of the transit service area, or which there is much in Atlanta, also affects transit ridership, but negatively [46].

Surveys of passengers on board transit vehicles yield additional insights into transit travel markets. Several of the multidestination bus/rail transit systems administered such surveys, and their results are similar. They show that the bus parts of multidestination rail/bus transit systems attract transit-dependent riders while the rail parts attract both transit dependent and choice riders. The large numbers of passengers who use combinations of buses and trains to complete their trips have characteristics almost identical to the passengers who use only buses [14]. In the context of the multidestination transit system attracting many more riders per capita than the radial systems, these results suggest that much of the added demand captured by the multidestination systems comes from the transit dependent. It appears that the demand for transit by the transit dependent population is highly elastic with respect to directness of transit service between origin and destination. Another study of persons going to work on an all-bus multidestination network in Broward County, Florida, confirms this point. It reveals that almost all of the workers are transit dependent and destined to employment throughout the metropolitan area. Transit travel time between origin and destination is the most important variable for influencing their ridership, and

Source: Brown and Thompson [45].

every 1% decrease in transit travel time between origin and destination increases transit-dependent riding by 2.7% [47].

These results suggest that metropolitan areas that invest in light rail systems achieve far greater transit performance than metropolitan areas that do not invest in light rail systems, if the metropolitan areas restructure their bus networks around light rail stations to reduce bus miles and achieve multidestination travel capability. Productivity will improve, cost efficiency will improve, and ridership per capita will increase. Added ridership will be a combination of the transit dependent and riders who have a choice for using an auto. Metropolitan areas that invest in light rail but do not do restructure their bus systems will not see such improvements in system performance.

This is a suggestive conclusion and not a hard-and-fast rule. There is the counter example of Salt Lake, which invested in a fast light rail line that connected a number of destinations together while not changing its CBD-radial bus system very much. The bus system was sparsely developed to begin with, and decision makers did not want to be accused of cutting back the already sparse CBD-focused bus system to pay for rail. The result was that the rail system attracted new ridership from previous auto users, and it also attracted about half of the bus system's ridership. The largely empty buses became even emptier. The light rail line looked like a winner, while the bus system looked like a loser [14]. The Salt Lake result is consistent with the thrust of a recent study of variables affecting rail transit ridership. That study concludes that the most important variable for increasing ridership is the magnitude of suburban employment within walking distance of rail stations. Rail lines that serve only employment in CBDs have low ridership, because most employment is located outside of CBDs. Rail lines with high ridership directly serve employment in many locations. The study concludes that multidestination rail networks serving large parts of regional employment are essential for attracting rail ridership but bus connections are irrelevant [48].

Consideration of Capital Investment

An unanswered question from the analysis of transit performance in US midsized metropolitan areas is whether the favorable light rail performance results are worth the investment in light rail systems. If annualized capital expenses per passenger mile were added to operating expenses per passenger mile, would light rail appear so attractive? Brown and Thompson did not include capital investments for either buses or light in their analyses, because there is no source from which to obtain capital investments in US or Canadian transit systems. In the absence of such a data source, one could attempt to estimate capital investment in a metropolitan area's transit system in a given year, but doing so is a huge task and rarely has been attempted [49].

One study that did estimate comparative capital costs between light rail and buses was Kain and Liu's 1999 study comparing transit development in Houston and San Diego [49]. Both metropolitan regions aggressively development transit over a period of years, Houston with express buses on busways and high occupancy vehicle (HOV) lanes on freeways, and San Diego with light rail lines, around which the regional bus system was restructured. Kain and Liu found that both metropolitan regions achieved comparable gains in ridership with comparable investment in transit fixed facilities and rolling stock, measured per passenger mile. In coming to this conclusion, Kain and Liu prorated only a portion of the cost of HOV facilities to transit passengers, because motorists also used the facilities. These results suggest that metropolitan regions that invested heavily in express bus on freeway or busway facilities, such as Houston, Minneapolis-St. Paul, Seattle, and Pittsburgh, may incur capital expenses per passenger mile as high or higher (as was the case in Houston compared to San Diego) as metropolitan areas investing in light rail systems, such as San Diego, Denver, Dallas, St. Louis, or Portland.

One may conclude, then, that light rail capital investment, if it is accompanied by a bus network restructuring, buys a much better-performing transit system than no capital investment over and above what is required to buy buses and bus maintenance facilities. The multidestination transit network resulting from the light rail investment carries many more passengers, and the increment of additional passengers comes from both the ranks of auto users and of the transit dependent, who now use transit much more frequently than when they were forced to use a system focused on downtown. Presumably, the transit dependent who

now use transit much more, and the former auto users experience greater welfare for having made the switch to transit. Are these results worth the capital investment? A benefit-cost analysis is required to answer that question, and at the moment the authors are aware of none to which to turn.

Suppose that it is decided to spend a certain amount of capital in a metropolitan region that would buy either a core light rail system, around which buses could be restructured into a multidestination network, or an express bus network, using busways and HOV lanes on freeways, all focused on the CBD. Many light rail critics claim that money would be much better spent on the latter. How does a light rail investment in fact stack up to an express bus investment? The next section addresses that question by turning to three actual cases.

Comparison of Light Rail and Express Bus Performance

Brown and Thompson [51] examined express bus and light rail performance in three metropolitan areas that operate both modes: San Diego, Minneapolis-St. Paul, and Pittsburgh. In San Diego, light rail has been the center of transit development in the southern part of San Diego County since 1978, but express buses and commuter rail are the enhanced mode in the northern part of the county. Light rail and express buses function quite differently in San Diego County. In the light rail corridors, light rail stations are the focus of transit activity. Local bus routes focus on light rail stations, and passengers transfer not only between buses and trains, but between buses and buses (Fig. 9). Two of the stations shown in Fig. 9, 12th and Imperial and Old Town, also are transfer points between light rail lines, and the Old Town station also accommodates transfers with commuter trains.

The express bus corridors in the San Diego area have much less interaction with the local transit network. Buses operate long distances from northern points to the San Diego CBD. Some of the express buses operate nonstop, but some of them leave the freeway at intermediate locations to serve important destinations and transfer stations with light rail and other bus routes. There is a large time penalty in doing so, because of heavy traffic congestion around the freeway on and off ramps, but the destinations are important enough to warrant the loss of time. Nonetheless, there is much less emphasis on express bus transferring with local bus lines than in the light rail corridors, and because of the time penalty associated with express bus stations, there are far fewer express bus stations than light rail stations.

Figure 9 shows the patronage results in the San Diego area. The area of each of the blue circles is proportional to transit passengers getting on and off vehicles. The figure shows that most passenger activity in the San Diego region is associated with the light rail stations. Express bus stations are considerably less important, even though they serve areas of heavy population and employment. Express buses in each of the two corridors to the north carry about 5,000 daily passengers in each corridor. The light rail corridor running from Old Town through the CBD to the border (the Blue Line) carries about 65,000 passengers per day. (The express bus that operated in the CBD to border part of this corridor until the light rail line opened in 1981 carried about 900 passengers per day.) The light rail line running from the CBD to El Cajon to the east (the Orange Line) carries about 25,000 passengers per day. Not shown in the figure is the eastern half of the newest light rail line in San Diego, which runs from Old Town east to El Cajon (the Green Line, operating through the west–east Mission Valley). Even though the Green Line does not serve the CBD, it does serve many other important destinations, including two regional malls, suburban office buildings, apartment and condominium complexes, complexes of big box stores, San Diego State University (SDSU in Fig. 9), and a sports stadium. It is carrying about 22,000 passengers per day [52]. By far the most heavily patronized transit stop in the region is not in the CBD but is the Old Town Station, where the Green Line intersects with the Blue Line running to the CBD and the south, numerous bus lines running to the northeast, north, northwest, west, and southwest, and a commuter rail line running to the north. A large park and ride lot also is located at the Old Town station. Before the Green Line was completed to El Cajon, the Old Town Station accommodated about 20,000 boarding and alighting passengers per day in 2005; that number increased to 32,000 daily boarding and alighting passengers in 2006 after the Green Line opened in its entirety. The second

Light Rail Transit, Systemic Viability. Figure 9
Transit lines and daily boardings and alightings at transit stops, San Diego 2005, a year before the full Mission Valley line opened [51]

most heavily patronized station in the region is the 12th and Imperial Station, which is the transfer point between the south (Blue Line) and east (Orange Line) light rail corridors. The 12th and Imperial station (called the Mills Center) handled about 22,000 boardings and alightings per day in 2006, and most of the passengers were transferring between the two light rail routes [14].

The top panel of Table 6 also shows the much greater productivity of light rail compared to express buses in the San Diego area. Express buses account for 12% of the revenue hours of transit service in the region but carry 7% of the transit passengers. The three light rail lines accounts for 7% of the revenue hours of transit service in the region but carry 33% of the transit passengers. These numbers illustrate what is

Light Rail Transit, Systemic Viability. Table 6 Express bus and light rail comparisons in three metropolitan areas. 2006 data

Transit service	Passenger trips	Revenue hours	Revenue miles	Trips per revenue hour[a]	Trips per revenue mile[a]

meant by light rail being the backbone of transit service, around which the rest of the transit system is organized. Tables 3–5 show that transit in San Diego is among the best performing of the transit systems in midsized US metropolitan areas.

The San Diego light rail and bus network is organized so that passengers could travel to many destinations in addition to those in the CBD. Most bus routes and one of the three light rail routes do not go to the CBD, and one could infer that most of their passengers are not going to the CBD, either. Even transit routes directly serving the CBD have most of their passengers going to other destinations, as shown in Table 7. Constructing Table 7 was possible, because the San Diego MPO keeps detailed records of passenger boardings and alightings for all stops for all transit routes at different times of the day. During the morning rush period, 65% of the riders of the two light rail lines directly serving the CBD did not get off in the CBD. They got off at other stations. Eighty-five percent of express bus riders, 68% of commuter train riders, and 77% of local bus riders got off at destinations other than the CBD. These figures indicated that a large market does exist for non-CBD transit service. The Canadian approach to transit network design, structuring bus routes around light rail lines serving numerous destinations, thus appears to be an approach to providing transit service that would yield much higher ridership and greater productivity than CBD-focused approaches, such as in the next two examples.

Minneapolis-St. Paul offers a different perspective, in that the region operates both light rail and express buses, but light rail is not the favored mode in that area. Since the 1970s, the area's transit provider, Metro Transit focused on connecting suburban neighborhoods to the CBD with express buses operating on freeways. Metro Transit has done an excellent job expanding the express bus system, and it is considered one of the more

progressive transit systems in the USA for its efforts in this regard. More than 90 of the region's 200 plus bus routes are express bus routes, and 85% of them focus on the Minneapolis or St. Paul CBDs. Figure 10 shows in heavy black lines the area's CBD-oriented express buses and light gray lines other bus routes. There also is a heavy investment in infrastructure to facilitate the express bus service. Express buses make use of 15 miles of busways, 38 miles of high-occupancy vehicle lanes, and 268 miles of bus-only freeway

shoulder lanes [51]. Metro Transit did not open a light rail line until 2004. The agency had opposed light rail transit but acceded to outside political pressures to build a line. To its credit it built a state-of-the art line, around whose stations it restructured local bus lines operating into the light rail corridor. The line serves not only the Minneapolis CBD, but also two stations at the international airport and a terminal station at the Mall of America, perhaps the largest suburban mall in the USA. The Minneapolis light rail line thus is multidestination in character. The light rail line and its stations also are shown in Fig. 10 [14, 51].

Express buses in the Minneapolis-St. Paul region are among the most productive in the nation [14]. Despite this, the express buses are not nearly as productive as the region's light rail line, as shown in the middle panel of Table 6. The express bus system accounts for 15% of the region's hours of transit service and carries 13% of the region's transit passengers. The one light rail line accounts for 3% of the region's hours of service but carries 11% of the region's transit passengers. The percentage may be higher today. The more recent daily light rail patronage figure for Minneapolis of 34,000 daily passengers in 2008, shown earlier in Table 1, indicates light rail passenger growth.

The trend of patronage for the overall transit system, however, has been downward, as shown earlier in Tables 3–5. The downward trend could be caused by decentralization. The transit system is exceptionally well run, and the region is progressive and growing. Service reliability and regional decline are not causes of transit decline. The region continues to decentralize, however, and the CBDs are becoming relatively if not absolutely less important as time passes. Metro Transit recognizes this point and is building more intermediate stations at emerging destinations along its express bus routes to tap new, non-CBD travel demands. Overall, however, the transit system in the Minneapolis-St. Paul region remains CBD-centric.

Pittsburgh also operates both light rail and express buses in a transit system where about 85% of total regional transit service connects suburban neighborhoods with the CBD. The transit system, the Port Authority of Allegheny County (PAT) invested in three busways and a light rail line. The busways are Type A grade-separated facilities that run to the south, east, and west from the CBD. Express buses coming from the suburbs funnel into the busways and head to the CBD. The busways cost several hundred million dollars to build, and each one was designed to serve up to 50,000 passengers per day. Actual usage is much lower, varying between 9,000 and 13,000 daily passengers, depending on the busway. The light rail line is a several hundred million dollar rebuilding of the South Hills streetcar corridor, including a subway in the CBD. Its primary purpose is to connect residential neighborhoods in the south of the city to the CBD. The line does serve a second destination, however, which is South Hills Village, a suburban shopping center. Unlike stations on the light rail line in Minneapolis-St. Paul, Pittsburgh light rail line stations are not focal points for local bus routes. Bus lines tend to parallel the light rail line into the CBD. The south busway also parallels part of the light rail line and uses the light rail Mt. Washington Tunnel to gain access to the CBD. Transferring between buses and light rail trains is difficult at suburban stations. Not only do few bus routes intersect with the rail route, but transferring passengers must pay a second fare on the vehicle to which they transfer [14, 51].

As noted earlier in Tables 3–5, the Pittsburgh transit system has been in decline. Its CBD focus may be the cause. Although population in the overall region has not been growing, it has been decentralizing. The CBD also has been losing employment relative to the rest of the region [14]. The CBD is the only market that the transit system has identified as being important to serve; thus, as the CBD declines, so does the transit system. Because of its isolation from the rest of the transit system, light rail in Pittsburgh is not as well used or productive as light rail is in many other US cities. Table 1 presented earlier shows its passenger density is among the lowest of light rail lines in the USA. Despite that, it still is more productive than the Pittsburgh express bus system, as shown in the bottom panel of Table 6. Express buses account for 22% of daily transit service hours in Pittsburgh and carry 19% of daily transit passengers. Light rail accounts for 4% of daily service hours and carries 11% of daily transit passengers.

Light Rail Traffic Density Related to Strategic Development of Light Rail Systems and to Land Use

Table 1 presents average light rail passenger densities. This section discusses traffic densities in the context of

light rail development strategies and land uses in several of the urban areas listed in the table, coming to conclusions about the relative effectiveness of those strategies in the context of different land uses. Traffic densities, for example, suggest that of the pioneer light rail systems, Edmonton and Calgary are highly successful, and that the systems in San Diego, and Portland are less successful, but on the other hand, they are relatively more successful light rail initiatives than those in San Jose, Sacramento, and Buffalo. The transit systems in Edmonton, Calgary, San Diego, and Portland all developed with similar visions of light rail serving as the core of multidestination light rail/bus networks. Differences in transit development strategy do not explain differences in traffic densities between the Canadian and US light rail systems, but differences in land uses may. Edmonton and Calgary are more compact metropolitan areas than San Diego and Portland, with fewer freeways and more apartment living. Distances between places where people begin and end trips are shorter. Such land use differences may account for the greater light rail traffic densities in the Canadian metropolitan areas compared to their US counterparts employing similar principles of transit development. Jones [11], on the other hand, argues that the higher transit ridership seen in Canadian cities compared to transit use of similar cities in the USA is due largely to lower personal income in Canada.

Higher light rail passenger densities in San Diego and Portland compared to those in San Jose, Buffalo, and Sacramento likely arise as a consequence of the role of the light rail lines in San Diego and Portland as the cores of their multidestination transit networks. Such strategic vision has been less well articulated in San Jose and Buffalo, and it has not been consistently embraced in Sacramento.

The traffic densities of Edmonton, Calgary, San Diego, and Portland light rail lines also equal or exceed the traffic densities of most of the older streetcar operations that have been rebuilt. Boston is the only older streetcar operation whose traffic density exceeds that of most of the modern light rail adoptions, and that is because many passengers use the Boston streetcar subway as a shuttle to their final destination after alighting from rapid transit lines, bus lines, and commuter trains. Hardly any buses serve the Boston CBD, and bus passengers destined to the CBD transfer to light rail or rapid transit lines. The light rail traffic densities of Edmonton, Calgary, San Diego, and Portland light rail lines are much greater to slightly greater than streetcar traffic densities in Toronto and San Francisco, two cities where the streetcars function as important parts of bus/streetcar/rapid transit integrated route networks. Toronto and San Francisco both are densely populated cities, and one would expect that their streetcar traffic densities are greater than they are relative to the lower-density, more sprawling metropolitan areas of Edmonton, Calgary, San Diego, and Portland because of their central city locations. However, streetcars in San Francisco (even in the subway) and in Toronto generally are much slower than the light rail lines, and slow speed may account for the lower-than-expected streetcar traffic densities in Toronto and San Francisco. Similarly, the subway-surface light rail lines in Philadelphia are both relatively slow and are not part of integrated bus/light rail networks.

Light rail traffic densities in Edmonton, Calgary, Portland, and San Diego greatly exceed the light rail traffic densities of Cleveland and Pittsburgh, which are other suburban light rail lines, but where there is no route coordination with buses. Cleveland and Pittsburgh operate CBD-radial transit systems. The light rail traffic densities in Edmonton, Calgary, Portland, and San Diego also greatly exceed the traffic densities of the New Orleans and Portland streetcars.

Similar patterns are exhibited by more recent light rail adoptions. Those that are characterized by bus systems being restructured around light rail lines (Dallas, Denver, Minneapolis, St. Louis) or where the light rail lines have been imbedded into bus grid networks (Los Angeles in the cases of the Blue and Green Lines but not the Gold Line) generally have higher traffic densities than those where bus/light rail integration does not exist (Baltimore, Pittsburgh, Hudson-Bergen).

The importance of the place of light rail in a multidestination bus network for high traffic density is illustrated by the Green Line in Los Angeles. As the Green Line in San Diego, Los Angeles' Green Line does not serve the CBD. It is an east–west crosstown line that runs in the median of huge freeway about 8 miles south of the CBD, and pedestrian access between its stations and surrounding land uses very difficult. The line does not serve directly any major trip generators and is

dubbed locally, "The line from nowhere to nowhere." Yet, it carries between 30,000 and 40,000 passengers per day. It operates entirely on a Type A right-of-way, is very fast, and at every station it intersects with a north–south arterial road, each one of which carries a long, frequent, heavily patronized bus line offering free transfers to and from the rail line. Transfer movements are heavy. The Green Line also connects with the north–south Blue Line, the first light rail line in the region. The Blue Line carries 75,000–85,000 passengers per day (the most heavily traveled single light rail line in the USA) because it is fast and because almost every station serves a major east–west arterial road, each of which hosts a long, frequent, heavily patronized bus line with free transfers to and from trains [53].

There are two light rail applications with lower traffic densities that restructured bus services around the light rail investments. Neither one disproves the proposition that multidestination transit systems achieved by restructuring bus networks around light rail investments improves transit performance. One of these is in St. Louis. St. Louis operates a fast light rail spine through the center of the metropolitan area serving the CBD and several other important destinations. Within the metropolitan area, the transit operator restructured bus routes around light rail stations, primarily to improve transit productivity rather than to create a multidestination network. The line, which originally terminated across the Mississippi River in East St. Louis, later was extended for about 20 miles into Illinois farmland to achieve equity of light rail investment on the Illinois side of the river. The extension dilutes light rail traffic density [33, 54]. Even so, the St. Louis line's patronage density is much higher than that of Pittsburgh and Baltimore. Light rail lines in Baltimore and Pittsburgh (as well as in Cleveland) compete with radial bus lines running to the CBD.

The fact that Cleveland's light rail traffic density is considerably higher than Pittsburgh's and Baltimore's when its service philosophy of serving the CBD is much the same may be related to both speed and land use. Cleveland's light rail line was built in 1920 to serve a series of neighborhoods that were designed concurrently, with the rail line in mind. The neighborhood design objective was the creation of short and attractive walks from all houses in the Shaker Heights development to streetcar stops. This factor may set it apart from light rail line in Baltimore, which is even faster but where favorable urban design around stations does not exist. The Pittsburgh line is somewhat slower than the Cleveland line, and its access to residents may not be as good, either.

The Oceanside-Escondido line is the remaining light rail line, around which bus services are structured, where traffic density is lower. Land uses may be the explanation. The line serves a sprawling, low density and hilly part of San Diego County almost 40 miles north of the CBD, offering service every 30 min with diesel rail cars. The area that it serves is more sparsely settled than the other areas considered, and the frequency of service is much less, as well. These attributes likely result in its low patronage density, even though there are high transfer movements between buses and trains at three transit centers along the line. The three bus transfer stations are the most heavily patronized stations on the line.

The examination of traffic densities in the context of transit service approach and metropolitan context suggests several points. First, it strengthens earlier conclusions that light rail being imbedded in a multidestination transit network is important for achieving high traffic density, which appears to be related to improved overall regional transit performance. The analysis also suggests that faster light rail lines that are backbones of multidestination transit networks perform much better than slower lines in a similar context. The message on the effect of urban form is mixed. Light rail experiences higher passenger densities in Calgary and Edmonton than in San Diego and Portland, even though all four metropolitan areas embraced similar transit development strategies, possibly because the Canadian metropolitan areas are more compact than their US counterparts. On the other hand, lower incomes in the Canadian cities may explain the difference. Urban form may influence higher-than-expected patronage for Cleveland's light rail line. On the other hand, high densities in Toronto and San Francisco do not translate into streetcar traffic densities that are higher than traffic densities for many of the new light rail lines serving much lower density, more sprawling metropolitan areas. The overall conclusion is that where light rail has been employed to take advantage of the high productivity characteristics that were bred into its technology, it has done

extraordinarily well for improving transit performance. Where policy makers have not made use of those characteristics, light rail has had a less favorable effect on transit performance.

Effects of Light Rail Investments on Land Use Patterns

As discussed earlier, growing automobile ownership weakened and all but eliminated the power of streetcar investments to affect metropolitan growth patterns around World War I. Giuliano [55] summarizes theoretical and empirical literature on why automobiles had that effect. Her argument is that transportation investments alter land use patterns when the investments make parcels of land relatively more accessible to jobs and employment than other parcels. More accessible parcels have higher rents and will be developed at higher intensities. When the streetcar era began, extension of streetcar lines into green fields around cities conveyed huge accessibility increases for those parcels. Streetcars thus had a large impact on the pattern of development. The automobile, however, conveyed high levels of accessibility to all parcels in metropolitan areas. After auto ownership in cites was widespread and roads around cities were paved, parcels of land served by streetcars no longer had an accessibility advantage compared to other parcels. All parcels in the metropolitan area had roughly equal accessibility, and so development spread out at low density. The star-shaped city morphed into the blob. Giuliano argues that the condition of relatively uniform accessibility continues today. Parcels proximate to new light rail transit stations are unlikely to have much of an accessibility advantage compared to other parcels and are unlikely to develop much differently if left to the whims of the land market. She then marshals abundant empirical evidence to show that rail transit investments during the post World War II period have had little if any effect on development patterns in US cities. Some other researchers, such as Bernick and Cevero [56] or Knaap, Ding, and Hopkins [57], examined whether property located in proximity to rail stations has fetched higher prices in comparison to similar properties not near rail stations and found that rail transit proximity does bring higher rents, but the effect is marginal. Others have surveyed residents of new transit-oriented developments built adjacent to light rail stations in Washington County west of Portland and Pasadena, California to determine the extent of light rail use. Both studies found that around 10% of residents use light rail stations, which is low but still higher than typical suburban residential areas [58, 59]. The effect appears to be the greatest for inner city parcels near stations on large, comprehensive rapid transit systems operating on right-of-way Type A, of which the Washington Metro is an example [60].

Portland's light rail line often is cited as the best example of light rail investment affecting land uses. The first line extended 16 miles from the CBD through medium to low density blue collar and middle income suburbs to the east and opened in 1986. Its opening was accompanied by planning and zoning policies that allowed higher density development around stations. Little redevelopment happened through the first 15 years of the lines' existence, except in one area called the Lloyd Center. Located across the Willamette River from the Portland CBD, Lloyd's Center was the original suburban mall in the Portland region. By 1986, it was starting to become run-down. After light rail arrived, commercial and government redevelopment started, and over time the Lloyd Center has become an eastside extension of the Portland CBD. It is included in the free fare CBD zone (formerly multimodal, but now limited to LRT and streetcar lines). The extension of light rail 16 miles to the west in 1999 was accompanied by stronger planning and zoning regulations that distinguished between transit-friendly and transit-hostile land uses (authors' terms). Only transit-friendly land uses were permitted near stations. Metro, Portland's regional government, also employed a developer who knew construction techniques for medium density residential complexes (in the range of 20–60 dwelling units per acre). His job was to teach these techniques to local developers, whose expertise was in low density residential or steel-framed high rise building. These changes resulted in some higher density residential redevelopment around stations on the original line and higher density residential development in green field sites along the new western line. Perhaps the biggest decision affecting land use, however, was to take light rail to where growth was happening rather than to naively think that light rail investments, wherever they were made, would attract development.

So, the transit district extended the west line into a region that already was growing very rapidly, both with new employment and new residences. Planners purposefully chose an alignment that offered many green field sites near stations. The net result of all of these actions is the construction of some higher density development connected with pedestrian paths and sidewalks to rail transit stations.

Another slightly different approach to achieving coordination between land use and light rail is to modify auto-oriented commercial development so that light rail can serve it. This also is an example of taking light rail to where growth is happening, rather than trying to entice growth to come to light rail. The City of San Diego and the San Diego MTDB followed this approach with the building of the Green Line through the Mission Valley. Mission Valley, running in an east–west direction about 5 miles north of the San Diego CBD, began attracting intense retailing and commercial development in the 1950s that largely replaced the CBD as the retailing hub of the region and rivaled the CBD as a commercial center. By the time MTDB designed the Green Line in the early 1990s, Mission Valley contained an east–west interstate freeway, an east–west high speed six lane arterial road, and crossings of four north–south freeways built to interstate standards. The valley also contained a regional mall, a mall of big box stores, other scattered big box stores, scattered high rise office building, smaller malls and strip malls, and a sports stadium. San Diego State University rose on the south wall of the valley toward its east end. Another regional mall was located just east of that and already was served by the Orange Line running from the CBD. There also were apartment complexes built on the floor of the valley and on its side. Running through the middle of all of this was the San Diego River, little more than an open storm drain that was dry most of the year but sometimes flooded. Light rail in the Mission Valley was part of a city-led remodeling of the valley. The city rebuilt the river into an attractive, natural-looking wetlands lined on both sides with swales. The light rail line was pieced together from sections of swales, from bits of access street rights-of-way, and from truck alleys serving the backside of mall buildings. The light rail line also used elevated structures liberally. To access San Diego State University, the Green Line dove into the side of the valley in a short subway, with a station directly under the university's bus transfer hub. The city built a pedestrian path along the river and connected it laterally to existing developments. MTDB built pedestrian connections from its light rail stations to the river path. The city also commissioned a nationally known architect, Peter Calthorpe, to design a new apartment complex centered on a light rail station in one of the valley's remaining green field sites. The development is called Rio Vista and is what is known as a Transit-Oriented Development, or TOD. The Green Line, which opened in late 2005, runs from the Old Town station on the west where it connects with numerous bus routes and two rail routes. It connects to another bus transit center at Fashion Valley mall adjacent to one of the freeways coming from the north. Express buses from the north call at this station, as do several local bus routes. It connects with another bus station at San Diego State University, still another bus station as the Grossmont Mall (where it joins the Orange Line from the CBD), and it terminates at still another bus station in El Cajon. The valley still is auto oriented, and most people who go there use autos. The difference is that transit now works there, as well (Fig. 11). The Green Line now is carrying about 22,000 passengers per day to and from valley destinations [52].

Conclusions

Light rail arose during the 1950s and 1960s as a new transit mode in northern European cities that provided higher quality, higher capacity, substantially more productive, and faster transit service than traditional streetcars and local buses. Light rail generally was cheaper to build than traditional subway and elevated railway systems, and as a consequence, it could be afforded by many midsized metropolitan areas that could not afford to build rapid transit lines. These qualities attracted the attention of advocates of transit and urban renewal in Canadian and US cities, leading to light rail's first North American adoption in Edmonton in 1978. Since then, 21 Canadian and US metropolitan areas whose transit systems operated only buses at the beginning of the 1970s opened one or more light rail lines in addition to buses.

The scope of light rail implementation in Canada and the USA also may be responsible for a renewal of

Light Rail Transit, Systemic Viability. Figure 11
The first section of San Diego's Mission Valley Line. Looking east in 2002 along the valley from a high rise building at the Hazard Station. Note train of U2 cars. Author's photo

interest in traditional streetcar investment. Eight Canadian and US metropolitan areas still operated streetcars in 1970 along with large bus systems. Six of these areas subsequently rebuilt their streetcar systems with at least some light rail characteristics, generally leaving out those characteristics that led to productivity improvement. One city with streetcars renewed and expanded its traditional streetcar operation as a traditional streetcar operation (New Orleans), using a mix of historic cars and replicas of historic cars with more modern electromechanical gear. (The eighth city, El Paso abandoned its remaining streetcar line in the early 1970s.) In the last several years, a few other cities built new streetcar lines primarily as tourist-oriented circulator lines in downtown areas. Some of the new lines use restored streetcars, some use replicas of historic cars, and some use modern European-designed articulated streetcars.

Results are mixed. Some of the light rail investments have had strongly positive results. They substantially improved regional transit performance in metropolitan areas such as San Diego, Portland, St. Louis, and Dallas by increasing per capita ridership, improving transit productivity, and stabilizing or decreasing real operating costs per passenger mile. In these metropolitan areas light rail investments have all or most of the following characteristics: light rail lines are significantly faster than local buses, they are long, and their outlying stations are loci of bus route restructuring. Some of the stations in each of these metropolitan areas also have large park and ride lots. In all of these metropolitan areas, light rail lines serve sectors of their respective regions that were experiencing robust growth in both population and employment before the onset of the Great Recession. Zoning and development codes favored denser development around light rail stations. As a consequence, some of the stations in several of these metropolitan areas have been surrounded by dense new development whose residents and employees can and do walk to light rail trains. In each of these metropolitan areas, light rail lines account for between 10% and 20% of the transit service in their respective metropolitan areas but carry 30–50% of the daily passenger miles of transit traffic. These systems clearly are reaping the productivity capability of light rail investments. It also appears that the larger the share of metropolitan area employment directly reached by light rail lines, the more favorable the impact of the light rail investments on all aspects of transit performance.

Light rail lines with such favorable design characteristics have limitations, however. They are powerless

to attract economic growth in depressed areas, for example. They also have not substituted for auto travel on a wide scale. The best performing systems (in San Diego and Portland) have achieved patronage per capita increases in the range of 30–50% over a 20 year period, impressive when compared to the bus patronage magnitudes and trends of most midsized US cities but not impressive when compared to the magnitude of auto use in US metropolitan areas. Autos and light trucks generally account for more than 90% of metropolitan travel, and even a 50% increase in per capita transit use makes little inroads into auto use [61].

Many light rail and streetcar investments result in less favorable results. Results are less favorable where light rail investments cover only limited parts of their metropolitan areas or are placed in depressed parts of metropolitan areas. Light rail and streetcar investments also are less effective where the resulting service is as slow (or slower) than local bus services, where the investments result in the operation of one-car trains (buses on rails), or where the investments result in staff being placed in each car of multicar trains to collect fares. They also are less effective where there has been no coordination of bus and light rail service. If some or all of these qualities are characteristics of the light rail investments, the investments may result in higher real operating expenses per passenger mile, lower productivity, and reduced patronage per capita. (The investments may possess compensating attractive characteristics, such as tourist appeal, or adding cache to a neighborhood.)

Future Directions

Continued light rail investments in US and Canadian cities are consistent with the idea of sustainability if benefits from the investments outweigh the costs of the investments. There are two types of light rail investments to be considered: those that result in improved regional transit performance, and those that do not.

Light rail investments that enhance regional transit productivity have the following characteristics: trains have lots of capacity; trains have lots of wide doors; multicar trains are operated by one person; proof of payment fare systems are used with free transfers to and from buses and between buses; rail routes are long and fast (short routes offer no time advantage over buses); part of the speed is achieved by trains wasting little time at intermediate stops boarding and deboarding large passenger loads, because passengers use all of the wide doors and do not pay fare-collecting personnel; rail stations serve important destinations in addition to CBDs; bus networks are restructured around light rail stations with a substantial part of bus mileage replaced by train mileage; restructured bus routes not only take passengers from residential areas to trains, but train passengers to important destinations located close to but not directly served by stations; rail lines are located to serve growing parts of metropolitan areas, and development in such areas is retrofitted so that passengers can walk between rail/bus stations and adjoining development. In short, light rail works well where planners place it within a region in such a way to make use of its high capacity, productivity, and speed characteristics.

Such light rail investments will enhance regional transit performance. The outstanding and unanswered question is whether they will do so sufficiently to make the light rail investment worthwhile. While the authors do not have quantified benefits from such light rail investments, they can enumerate the categories of benefits and leave it to the reader to judge their significance. To begin with, benefits include consumer surpluses to transit dependent persons who choose to use restructured transit service to reach more quickly destinations throughout metropolitan areas. Benefits also include consumer surpluses to previous auto drivers who find it more convenient to switch to light rail services. Benefits also include fuel savings and pollution reductions resulting from fewer auto trips. There are two categories of fewer auto trips. One category includes previous auto trips made by those who now leave cars at homes or in suburban lots. The other category includes previously chauffeured auto trips of those without cars (perhaps friends and relatives were the chauffeurs). Such trips often involve considerable driving by the chauffeur to pick up the rider at a remote location or to return to the chauffeur's place of residence or work once the rider is dropped off. The elimination of such trips could reduce considerable regional auto and light truck VMT. Another significant saving is the value of time saved by previous chauffeurs. Still other benefits include lower real operating expense per passenger mile carried on the transit systems.

Other benefits include option value to environmentally conscious citizens who value having a multidestination transit network that they might wish to use some day. The aggregate of such benefits, in the authors' opinion, could outweigh resources required to build regional light rail systems that will enhance transit system performance.

The other category of light rail investments does not enhance regional transit performance. Light rail lines belonging to the second category typically are designed as just another slow bus route to the CBD, having no transfer connections with bus lines, no free transfers, displacing no bus miles, and either operating only one-car trains, or having drivers collecting fares on each car of multicar trains. Such lines have little justification. They will not perform well, and neither will the overall transit system. They probably are not consistent with sustainability.

In summary, a midsized metropolitan area into which light rail is introduced to take advantage of its high capacity, productivity, and speed characteristics can achieve substantial patronage growth per capita, improve productivity, and stabilize real costs for moving passengers within a metropolitan area. Stations can be nodes for development if they are located where development activity of the private market is active. Planning intervention in such areas can create attractive development that is accessible by transit, although autos will remain the principle form of access for some years into the future. Accounting for as few as 10% of regional transit service, such light rail lines can carry 30–50% of regional transit passenger miles that continue to grow year by year. Over time auto-less, middle-class subcultures could evolve around such systems. The benefits of such systems might outweigh their construction costs. If they do, this category of light rail investment is consistent with the concept of sustainability.

C3 Grasses Grasses possessing the C3 photosynthetic mechanism, so called because the first product of carbon fixation contains three carbon atoms.

C4 Grasses Grasses possessing the C4 photosynthetic mechanism, so called because the first product of carbon fixation contains four carbon atoms.

Cellulose Component of plant cell walls made up of chains of D-glucose (C6 sugar) molecules linked via hydrogen bridges consisting of 42% carbon (C), 6% hydrogen (H), and 52% oxygen (O).

Hemicellulose Heteropolysaccharide that contains various different sugar monomers such as glucose, xylose, mannose, galactose, rhamnose, and arabinose. Hemicellulose contains mostly D-pentose or so-called C5 sugars and is found in plant cell walls.

Energy crops Crops grown for the purpose of producing biomass for energetic use.

Energy grasses Perennial grasses with high biomass potential which can preferentially be harvested once a year at low moisture content.

Fischer-Tropsch diesel Biofuel produced from lignocellulosic biomass via a multi-step process. Gasification produces synthesis gas, which is cleaned and then transformed to liquids at high temperature and pressure by Fischer-Tropsch catalysis.

Lignin Complex three-dimensional polymers built from phenylpropane derivatives consisting of 64% carbon, 6% hydrogen, and 6% oxygen.

Rhizomes Underground shoot systems in perennial grasses serving as overwintering organs and for storage of nutrients.

Short rotation coppice (SRC) Fast-growing trees, such as poplar or willow, harvested in cycles of 3–5 years and which regrow from the stools after harvesting.

Definition of the Subject

More than 90% of the dry matter of lignocellulosic biomass consists of the three biopolymers: cellulose, hemicellulose, and lignin. Cellulose is made from chains of D-glucose molecules linked via hydrogen bridges. It is composed of 42% carbon (C), 6% hydrogen (H), and 52% oxygen (O). Cellulose is the most common organic substance found in nature and forms the structural component of cell walls. Hemicelluloses are polysaccharides, which have shorter chains of sugar units than cellulose. They have various functions in the plant including support and holding together the cell membranes. Lignin is a complex three-dimensional polymer built from phenylpropane derivatives, which is stored between the cellulose fibrils to strengthen the cell wall. It consists of 64% C, 6% H, and 6% O.

Lignocellulosic energy crops are characterized by the high lignin and cellulose content of their biomass. Lignin in particular is very suitable for direct combustion due to its high carbon content. Direct combustion as a solid fuel is therefore the preferred use of lignocellulosic biomass so far. But applications based mainly on the use of the cellulose fraction are also promising future energetic applications. These include the production of biofuels such as ethanol produced via enzymatic hydrolysis and diesel produced via gasification and Fischer-Tropsch synthesis.

Introduction

There are two groups of plants that are suitable as energy crops delivering lignocellulosic biomass: trees and grasses.

Forest trees have been delivering firewood for hundreds of thousands of years. The term "energy crops," however, refers to trees that are grown on agricultural land. Compared to forest trees, which are harvested after decades, trees grown as energy crops are harvested in cycles of 3–5 years. After harvesting, they can regrow from the stock up to five or more times. Therefore, this system of wood production is called "short rotation forestry" or "short rotation coppice" (SRC). Trees species suitable for SRC should show three main characteristics: Firstly, they need to be able to regrow from stools after cutting; secondly, they should produce several branches from the stool; thirdly, they need to show the maximum growth increment in the first year to achieve high biomass yields [1]. Tree species most suitable for SRC in temperate climates are willow (*Salix* ssp.) and poplar (*Populus* L).

Grasses suitable for the production of lignocellulosic biomass are characterized by their ability to concentrate high biomass yields in one cut. Many perennial grasses that are used for fodder production have a high

biomass yield potential, but this has to be exploited in multiple harvests (up to five times a year) of green biomass. Energy grasses for the production of lignocellulosic biomass are generally harvested once a year, often at the end of the winter period in early spring. At this time of the year, the harvested biomass is dry and of high quality. This refers to the low content of substances hindering the combustion process, such as ash, chloride, or potassium. These grasses are highly lignified, which allows for the late harvest. Screenings of various perennial grasses have identified three as the most suitable for lignocellulosic biomass production in temperate regions: *Miscanthus*, switchgrass, and reed canary grass.

In the following chapters, the characteristics and systems for the production and supply of lignocellulosic biomass from willow and poplar SRC and the most relevant energy grasses are described.

Short Rotation Coppice (SRC)

Willow and poplar have been identified as the most promising trees for SRC in European temperate climates, mainly due to their high yield potentials. Both belong to the family *Salicaceae*. Most species in the *Salicaceae* family show the characteristics important for SRC plantations. They are pioneer trees with a vigorous juvenile growth, the ability to root from the rods and to regrow from the stools [1].

There are about 300 species of naturally growing willow in the northern hemisphere, but only a few with a growing pattern suitable for SRC willow plantations [2]. Most clones used belong to *Salix viminalis* and *Salix dasyclados*.

The genus *Populus* is separated into six sections, of which *Aigeiros* (Balsam poplar), *Tacamahaca* (Black poplar), and *Leuce* (aspen) are most suitable for SRC.

Presently, there is a maximum of 20,000 ha of willow SRC in Europe, most of which are in Sweden where the biomass is fired in heat or combined heat and power plants. Sweden has the most practical experience with SRC willow, and therefore, the following description of the production and provision of lignocellulosic biomass from SRC is mainly based on the Swedish experiences. The production of poplar as SRC is still at an experimental stage.

Demands and Variety Choice

The main distribution area of *Salicaceae* lies in the temperate zones of the northern hemisphere, but extends from the subpolar area to the north to the subtropical and tropical area to the south.

Willow and poplar can grow on a wide range of soils, but a good water supply is important. To produce high biomass yields, the available rooting zone should be at least 60 cm. Willows prefer cool weather and are therefore most suitable for cool-humid climates. Poplars have higher temperature demands. Although willows have a higher yield potential, poplars can outyield willows on sites with less suitable growing conditions, such as shallow soils or limited water supply.

Black poplars are the most demanding species with regard to nutrient and water supply and temperature but, together with aspen, have the highest yield potential (Table 1).

Breeding activities, mainly performed in Sweden, have resulted in a set of willow varieties for specific conditions. "Tora" is a high-yielding variety that is very frost tolerant. In addition to frost tolerance, varieties were also selected for drier land – which under Swedish conditions means up to 610 mm precipitation. "Todis" and "Inger" are examples of varieties with lower water demands [2]. There are also various varieties that have been bred for resistance to rust or leaf beetles.

A few willow varieties and 71 genotypes again six pathotypes of the fungus *Melampsora larici-epitea* have been tested [3]. Among others, the varieties "Bjorn" and "Tora," were highly resistant.

Propagation and Establishment

SRC are planted from March to June, and planting should take place as early as possible to allow for good establishment. In preparation for planting the fields should be ploughed and harrowed deeply (6–10 cm) to clear the fields from weeds. One-year-old SRC willow rods serve as planting material. These are cut during the winter and stored at −4°C in a cold storage room until they can be planted out. The planting width depends on the harvesting system. The Swedish system stipulates a twin row formation where the distance between the rows alternates from 75 to 150 cm. The distance between the plants in the rows

Lignocellulosic Energy Crops, Production and Provision. Table 1 Agronomic characteristics and demands of *Populus* (poplars and aspen) for SRC according to Kauter et al. (2003) [1] (Data from 0 [low] to ++++ [very high])

		Botanical section		
		Aigeiros (black poplar)	*Leuce*, subsection Trepidae (aspen)	*Tacamahaca* (balsam poplar)
Local characteristics	Soil characteristics	pH > 6, deep soils with good and constant water and oxygen supply	Tolerates stagnant water and hydromorphic soils	pH 4.5–6.5, tolerates water to some degree, lower demands than Aigeiros
	Soil nutrient supply	++++	++	+++
	Water supply	++++	+++	+++
	Mean temperature in vegetation period	++++	+	+++
	Vegetation period (days)	>150	>120	>130
Sensitivity to	Early and late frost	+++	+	+++
	Dense stands	++++	+	0
Increment	Peak mean annual increment at age of (years)	10–15	10–15	4–10

is approximately 59–65 cm. About 13,000 cuttings per hectare are planted. There are two principal planting systems: either cutting and planting the willow rods (1.8–2.4 m long) in one process or planting rods (18–20 cm long) which have already been cut. Once planted, the cutting is pressed down into the ground so that only 1–2 cm protrudes above ground level in order to provide it with good soil contact and minimize the risk of drying out [2].

Fertilization

Various field trials have shown nitrogen fertilization to have little or no effect on biomass yield [4]. Investigation of yield effects of nitrogen fertilization in SRC has shown that willow reacts more strongly to fertilization than poplar and shows increased biomass production [5]. Willow plantations can be fertilized with mineral fertilizers, but also tolerate organic fertilizers. In Sweden, municipal wastewater or sludge is applied to fertilize willows and is thus cleaned in the process [6].

In the plantation year, no nitrogen fertilization should be applied because it strengthens the competing weed. In the following year, it is recommended that fertilizers are applied according to the withdrawal by the harvested biomass, which is about 4–7 kg nitrogen (N), 0.8–1.8 kg phosphorous (P), and 2.5–4 kg potassium (K) per tonne dry matter [7].

The efficient use of nutrients by SRC can be explained by the nutrient cycle in the trees as shown in Fig. 1.

Nutrients accumulated in the leaves are recycled when fallen leaves decay and release these nutrients into the soil. Over winter, parts of the nutrients are also stored in the stems and roots of the trees. Because the vitality of the trees depends on this nutrient cycle, SRC should only be harvested when the leaves have been shed.

Crop Protection

The good establishment of SRC is important to guarantee highest yields. In the first year, establishment is threatened by weed competition, and therefore, intensive weed control needs to be performed. For this purpose, herbicides can be used or weed control can

Lignocellulosic Energy Crops, Production and Provision. Figure 1
Nutrient cycling in 4-year-old poplar trees

be performed mechanically at a later stage. If weed competition is strong, weed control may also be necessary in the second year.

Game grazing can damage plantations significantly in the year of establishment. Therefore, planting SRC in the vicinity of forests should be avoided. At endangered locations, fencing may become necessary. Once the plantations are established, grazing is generally limited to the outer rim of the plantation [2].

Of the various insects that feed on SRC (e.g., gall midges, aphids, leaf beetles), leaf beetles can cause the most damage. If necessary, they can be controlled by pesticides. There are also several willow varieties available which show resistance to leaf beetles [2].

The fungal infection, leaf rust, can also lead to significant damage in SRC as it causes leaves to wither and fall prematurely. Through the Swedish breeding program, several varieties with good or total leaf rust resistance have become available.

Harvest and Densification

In the winter, after planting, the shoots have to be cut back to allow the formation of multiple shoots growing from the stools. This measure improves yields and can be performed using a mower.

The harvest can take place once the woody biomass has reached about 25 t dry matter per hectare or the stem diameter at the base is 6 cm. This is usually the case when the shoots are 3–4 years old [2].

To maintain vitality and to improve re-sprouting, harvesting must be performed during winter (November to April) when the leaves have been shed. There are various kinds of harvesting machines. Conventional SRC harvesters can cut and chip the stems in one procedure. For this purpose, a modified forage harvester that cuts and chips the branches through a specified cutting module can be used [8]. Other systems apply a modified sugar-cane harvester or a front hydraulic driven mow-cutter [7]. The chipped material is blown into a trailer alongside the machine as it moves through the crop. In another harvesting system, sticks are cut with one pass of either a self-propelled or trailed machine. The sticks are laid at the field rim from where they are loaded onto a tractor and transported to the store. Because the harvested biomass contains around 50% water, the advantage of this system is that the water content

decreases while the sticks are stored and they can be stored without decomposition.

Yield and Quality

Information on yields from SRC given in publications varies greatly. In Sweden, a yield of 8–10 t dry matter ha^{-1} a^{-1} can be reached in well-managed and pest-free plantations [2]. In field trials at several German locations, large yield differences between locations and varieties were measured. The ten highest yielding varieties produced from 8 t dry matter (black poplar variety Max 2) to 11.5 t dry matter (black poplar variety Raspalje) [9]. But similar to reports from Belgium [10], low yields of 3.5 t ha^{-1} a^{-1} were also measured when less productive varieties or drier sites were employed [9]. Sometimes poplar varieties yielded significantly higher than willow [9]. However, when new willow varieties such as "Tora" are grown on fertile soils with good water supply, dry matter yields of up to 15 t ha^{-1} a^{-1} were harvested [4].

Table 2 gives an overview of the composition of willow and poplar biomass.

Lignocellulosic Energy Crops, Production and Provision. Table 2 Biomass characteristics of willow and poplar

Component in% of dm[a]	Tree species	
	Willow	Poplar
Lignin	20.0	23.2

[a]dry matter

Lifetime of a Plantation and Removal

The economic life of a well-managed SRC plantation is typically up to 20–25 years, which means that an SRC plantation can be harvested about 5–6 times during its lifetime.

To convert land under SRC willow back to agricultural land, spraying the plantation with a mixture of glyphosate and MCPA while the shoots are growing in summer is recommended [2]. This kills the stools which can then be cut up with a heavy disc tool or mulched and ploughed in.

Energy Grasses

Miscanthus, switchgrass, and reed canary grass have been described as the most important energy grasses for temperate regions [15]. They differ from each other in origin, eco-physiological demands, and biomass quality.

The genus *Miscanthus* consists of 17 species and can be divided into four sections [16]. The genetic origin of *Miscanthus* is East-Asia, where it is found throughout a wide climatic range from tropical and subtropical parts of Southeast Asia to warm temperate parts of the Pacific Islands. The genotype widely used in Europe, *Miscanthus x giganteus*, was introduced from Japan to Denmark in 1930. *M. x giganteus* is a triploid (2n = 3x = 57), natural hybrid from *M. sinensis* and *M. sacchariflorus*.

Switchgrass (*Panicum virgatum* L.) belongs to the subfamily Panicoideae of the Gramineae family. It is native to North America where it occurs naturally from a latitude of 55° N down to central Mexico. It is one of the grasses that dominated the North American tallgrass prairie.

Reed canary grass (*Phalaris arundinacea* L.) belongs to the subfamily Pooideae of the Gramineae family. It is native to the temperate regions of Europe, Asia, and North America. In Europe, it can be found throughout the Nordic countries, even in the mountainous areas of the North. It is normally found in wet areas such as lakeshores and along rivers.

There are an estimated 30,000 ha of *Miscanthus* being grown for the production of lignocellulosic biomass in Europe, mainly in the UK, Austria, Switzerland, and Germany. The largest application of *Miscanthus* in Europe is currently the co-firing of *Miscanthus x giganteus* biomass with coal. The world's largest area under production with *Miscanthus* is probably found in China, where 400,000 ha of the species *Miscanthus lutariariparia* growing naturally around the coastal area of Dongting Lake are used for the production of low-quality paper. Reed canary grass is used as a forage crop mainly in North America, but also to some extent in Eastern Europe, Scandinavia, and Japan. Its use as a forage crop is decreasing due to the low feed value of the lignin-rich biomass. But, in more northern and cooler regions of Europe, it is increasingly used to deliver lignocellulosic biomass for solid fuels or pulp and paper production. Switchgrass is the main energy grass in Northern America.

Reed canary grass is a so-called C3 crop, and *Miscanthus* and switchgrass are C4 crops. In contrast to C3 crops, C4 crops are characterized by greater water-use efficiency (WUE) – up to twice that of C3 crops – and a higher biomass production potential [17]. However, this is not the case for very cool regions such as Sweden and Finland where low temperatures limit the photosynthetic process. Here C3 grasses perform better. For this reason, reed canary grass is the most suitable perennial grass for cooler, northern parts of Europe. But in temperate to warmer regions, *Miscanthus* by far outyields reed canary grass.

The processes of production and supply of lignocellulosic biomass from *Miscanthus*, switchgrass, and reed canary grass and the differences in the management of these grasses will be described in the following chapters.

Demands and Variety Choice

The standard genotype *Miscanthus x giganteus* can be grown on a wide range of soils. The highest yields are produced on soils with a good water-holding capacity. Sites with stagnant water are unsuitable. *M. x giganteus* begins growth from the dormant winter rhizome when soil temperatures reach 10–12°C. Leaf expansion occurs at temperatures between 5°C and 10°C, depending on the genotypes [18]. The main problem of *Miscanthus* production in Northern Europe is the poor overwintering of the rhizomes of the productive genotype *Miscanthus x giganteus* in the first winter after planting. Freezing tests have showed that *M. x giganteus* rhizomes removed from the field in January are killed at temperatures below −3.5°C while the rhizomes of *M. sinensis* survived up to −6.5°C [19]. *M. sinensis* genotypes are more winter-hardy than *M. x giganteus*, but they have lower yields than *M. x giganteus* and are therefore only chosen for regions where winter temperatures are too low to secure the survival of *M. x giganteus* plantations. Below, the term *Miscanthus* will be used as a synonym for *M. x giganteus*.

Switchgrasses are divided into upland and lowland ecotypes. The upland ecotypes are most commonly octaploids (2n = 8x = 72) or occasionally hexaploids (2n = 6x = 54). They are shorter, one-stemmed, and are more adapted to drier habitats [20]. The lowland ecotypes are predominantly tetraploid (2n = 4x = 36), coarse-stemmed, tall-growing, and have a more bunchy-type growth. They are more adapted to wetter sites, being found on floodplains, and are later maturing than upland ecotypes [20]. Due to their high yields for bioenergy production, the most promising cultivars for the USA are "Alamo" for the deep South, "Kanlow" for mid-latitudes, and "Cave-in-rock" for the central and northern states [21]. Kanlow and Alamo are lowland ecotypes while Cave-in-rock is an upland ecotype. There is not yet enough field experience with switchgrass in Europe to recommend varieties for specific site conditions, but Kanlow as well as Alamo has performed satisfactorily under European conditions.

Different upland and lowland switchgrass varieties have been tested with respect to their dry matter yields [22]. To this end, 15 varieties in Italy and 10 varieties in Greece were cultivated. In general, the lowland varieties "Kanlow" in Greece and "SL 93-3" in Italy produced the highest dry matter yields with 17.1 t ha^{-1} a^{-1} and 20.0 t ha^{-1} a^{-1} respectively.

Reed canary grass is a highly self-sterile allotetraploid plant (2n = 4x = 28) [23]. There is a large variation in morphological characteristics between, as well as within, different ecotypes. Several commercial varieties for forage purposes are available on the market, mainly in United States, Canada, and Eastern Europe. The recent novel application of this grass for material and energy uses means that

Lignocellulosic Energy Crops, Production and Provision. Table 3 Propagation and establishment methods for selected perennial grasses [15, 25]

		Seed establishment		Rhizome establishment		
		In the field	Pre-culture in greenhouse	In the field	Pre-culture in greenhouse	Micro-propagation

	Switchgrass	C	X			
	Reed Canary Grass	C				
Estimated costs [Euro ha^{-1}]		120–400	1,500–3,000	3,200	3,000–6,000	3,000–8,000

X = safe method; C = currently performed method for this grass

new types of cultivars need to be developed with lower nitrogen and potassium contents and higher lignin contents [24].

Propagation and Establishment

Establishment of plantations of perennial grasses is often the most expensive and critical step in the production process, because poorly established stand will produce lower yields and are susceptible to weed competition over several years. Table 3 gives an overview of methods for the establishment of the perennial grasses discussed here.

Because *M. x giganteus* is triploid, it cannot form fertile seeds and has to be propagated vegetatively via rhizome cuttings or micro-propagation. Both methods are currently practiced. For rhizome propagation, mother fields have to be "harvested" by cutting the rhizomes mechanically, picking them up by machines (e.g., potato harvesters) and spreading them mechanically over the new fields. Here they have to be ploughed in immediately to prevent them drying out. Rhizome pieces suitable for propagation need a size of 5–8 cm and two living buds. In micro-propagation, apical meristems are transferred into sterile culture and are propagated in vitro in nutrient solutions enriched with phytohormones. Miscanthus fields are planted in April to May – depending on the temperature conditions – with a density of two plants per m^2. Rhizomes can be spread evenly or, as done with the micro-propagated plantlets, planted at a row width of 70 cm.

Switchgrass and reed canary can be established via seeds, which is the establishment method with the lowest costs. Because switchgrass seeds often have a high degree of dormancy, they need to be treated before sowing to break this dormancy. For this purpose, they can be soaked and then stored in a cool place for 24 h to drain. Afterward they are kept in a refrigerator at about 3.5–5.5°C for 4 weeks. Switchgrass can be drilled in a conventional seedbed or no-till seeding methods can be used. Seeds can be broadcast or drilled in rows. As light-seeded species, they should not be placed deeper than 1–2 cm [17]. For no-till planting, less seed (9 kg ha^{-1}) is required than for conventional seeding (11 kg ha^{-1}). A row spacing of 80 cm is recommended.

Best stands of reed canary grass are obtained when sown not deeper than 1–2 cm in a well-prepared, firm seedbed. A row spacing of 12.5 cm and seeding rate of 15–20 kg ha^{-1} is recommended.

Fertilization

As shown in Fig. 2, perennial grasses have an internal system for nutrient recycling. The rhizomes, their overwintering organs, serve also as a nutrient storage. In spring, shoots emerge from these rhizomes and are supplied with nutrients from the rhizome. In autumn, a significant proportion of these nutrients are transferred back to the rhizomes to be stored for the following vegetation period.

Thanks to this nutrient recycling system and the efficient C4 photosynthesis process, the C4 grasses

Lignocellulosic Energy Crops, Production and Provision. Figure 2
Nutrient recycling in perennial grasses

Miscanthus and switchgrass have a low demand for nitrogen fertilization. There are reports that nitrogen fertilization has no effect on yields of *Miscanthus* and switchgrass or only up to the first 50 kg nitrogen ha^{-1} a^{-1} [15, 20]. The effect of nitrogen fertilizer, however, is very site specific. It is recommended that nitrogen fertilization, which is effective only on poorer quality sites, should be applied there at levels of 50 to a maximum of 70 kg nitrogen ha^{-1} a^{-1} [15, 26]. In the year of establishment, no nitrogen fertilization should be applied because it mainly leads to higher weed competition. The requirement for potassium (K), calcium (Ca), and phosphorus (P) fertilization should be calculated according to their withdrawal with the harvested biomass, which is about 0.7 kg phosphorous, 0.9 kg calcium, and 1 kg potassium per tonne dry matter.

Experience from Swedish field trials resulted in the following recommendations for the fertilization of reed canary grass for the production of lignocellulosic biomass. In the year of sowing, an amount of 40 kg nitrogen (N), 15 kg phosphorous (P), and 50 kg potassium (K) ha^{-1} is optimal for a good establishment of the crop. The year after sowing, the most economic result is reached by applying 100, 15, and 80 kg ha^{-1} of N, P, and K respectively. In the following years, the fertilization rates can be decreased if the delayed harvest system is applied, due to the translocation of nutrients at the end of the growing season and leaching during the winter. Recommended rates are 50, 5, and 20 kg ha^{-1} of N, P, and K respectively in spring [15].

Crop Protection

Presently, there are no reports on relevant pests or diseases in perennial energy grasses. The main demand for crop protection is the control of weeds in the year of establishment, due to the slow emergence of the seeds of switchgrass and reed canary grass and the large row distances in *Miscanthus*. As a preventive measure, the field should be ploughed before sowing or planting the grasses. There are various herbicides suitable for use in maize or other cereals which could be used, but there are different national regulations on the licensing of these herbicides for use in perennial grasses. Because *Miscanthus* has large row distances of 70 cm, mechanical weed control through hoeing is a common practice. In switchgrass, a reduction of weed competition can also be achieved by occasional clipping at 6–9 cm height [27].

Harvest and Densification

The lignocellulosic biomass from perennial grasses is harvested in early spring to give a dry biomass. The most suitable date for harvest depends on weather conditions and is ideally when the biomass has a moisture content of less than 20%. But harvest should be performed before emergence of the new shoots. Delayed harvest decreases biomass yields by about 30%, mainly due to leaf abscission. As leaves are rich in ash and substances such as nitrogen, potassium, and chlorine, which are deleterious to the combustion or biomass conversion processes, a reduction in the number of leaves improves the quality of the harvested biomass. This improvement is also enhanced by the leaching of water-soluble substances, such as chlorine, by precipitation in winter.

The most common method of harvesting of biomass from energy crops is cutting with a mower and subsequent baling [15]. Switchgrass and reed canary grass can be harvested with conventional haying equipment [28]. If the biomass is to be used or further densified nearby, *Miscanthus* biomass can also be harvested with a maize chopper. Due to the high silica content of *Miscanthus*, an especially hardened steel needs to be used for the knives. However, *Miscanthus* chips have a very low density and are therefore not suitable for transport over large distances. For combustion in small-scale units, *Miscanthus* biomass is harvested as chips and then pressed to briquettes.

Lignocellulosic Energy Crops, Production and Provision. Table 4 Typical ranges for the composition of biomasses from *Miscanthus*, switchgrass, and reed canary grass (winter harvest)

Component in % of dm	Grass species		
	Miscanthus	Switchgrass	Reed canary grass

Yield and Quality

The yield of lignocellulosic biomass depends on the site on which the biomass is produced.

As a C3 grass, reed canary grass has the lowest yield potential. For Sweden, a harvestable yield of 8–12 t dry matter ha^{-1} a^{-1} has been determined.

An analysis comparing *Miscanthus* and switchgrass has shown that the yield potential of *Miscanthus* is significantly higher (30–50%) than that of switchgrass [29]. An overview on yields for energy grasses shows that these range for *Miscanthus* from 4 t dry matter ha^{-1} a^{-1} in Northern Europe to 44 t dry matter ha^{-1} a^{-1} harvestable in Southern Europe and from 12 to 26 t dry matter ha^{-1} a^{-1} for switchgrass in the USA – both for one late harvest per year [15].

Whereas reed canary grass stands are nearly fully productive from the first year on, *Miscanthus* and switchgrass stands do not reach their peak yields until the third or fourth year. The oldest productive stands of *Miscanthus* are over 20 years old. Switchgrass stands can reach a productive period of 15 years and reed canary grass 10 years before yields decrease significantly.

The quality of the harvested biomass differs between the grass species and varieties and is strongly influenced by the harvest date. In addition, site conditions (e.g., mineral content of the soil) influence biomass quality. Table 4 gives an overview of the typical ranges in the composition of lignocellulosic biomasses from perennial grasses harvested in a delayed harvest system (i.e., in winter or early spring).

Future Directions

SRC and energy grasses are still very young crops and little breeding has so far been performed. For this reason, not many varieties are available for the biomass producer to match the demands of specific site conditions or specific biomass uses. In order to develop lignocellulosic energy crops successfully, further breeding programs targeting higher and more stable yields,

improved biomass quality, and adaptation to specific site conditions are required.

The major bottleneck in the production of perennial lignocellulosic crops is their establishment in the field. Establishment costs are high when propagation is performed vegetatively via rhizomes or micropropagation and deter farmers from producing these crops. Additionally, the establishment success is hampered by the low competitiveness of the crops in the year of establishment and through other factors, such as frost. Therefore, the development of safe establishment methods is an important prerequisite for large-scale implementation of these crops.

All perennial lignocellulosic energy crops display a good ecological profile because of

- Very low demands for nitrogen fertilization
- Perennity, which leads to long periods of soil rest and soil carbon accumulation
- The very high energy input-to-output ratio and greenhouse gas saving potential due to low nitrogen fertilizer demand and high yields

With the general demand for more sustainable energy-crop production, perennial lignocellulosic energy crops will play a major role in future bioenergy production. Combined electricity and heat production is the main area for which lignocellulosic energy crops are suitable and where they can be applied in the short term. Future options also include the production of next generation biofuels.

Glossary

Dish Short for point focusing concentrator with circular paraboloid reflector.

Heliostat The reflecting device that is positioned such that it reflects the direct sun light to the receiver.

IAM Incident angle modifier: optical efficiency at a certain angle of incidence in relation to the optical efficiency at normal incidence.

Longitudinal Parallel to the direction of the receiver.

Longitudinal IAM IAM for incident rays with no transversal component.

Receiver The device, usually a tube or a bundle of tubes, that absorbs solar radiation and transfers it to useful heat.

Reflector Here sometimes used synonymously with "mirror" or "heliostat".

Tower Here used as a short form for solar power tower or central receiver system.

Transversal Perpendicular to the direction of the receiver and parallel to the aperture.

Transversal IAM IAM for incident rays with no longitudinal component.

Trough Linear concentrating collector with parabolic reflector trough.

Definition of the Subject and Its Importance

Linear Fresnel Collectors are a subgroup of linear concentrating collectors. They use linear receivers and reflectors, which are segmented in single axis tracking heliostats. The reflector segments are typically aligned horizontally and track the sun such that the receiver is illuminated without need to be moved (see Fig. 1).

Similar to heliostat fields in tower projects Linear Fresnel reflectors allow for a much bigger aperture area per unit of receiver compared to the ideal reflector that is, the parabolic trough. The mechanical size limits of ideal reflectors (due to wind load and weight) are similar for each individual heliostat as for a trough. The beauty of heliostat systems is of course that the aperture size of a complete system is independent of the

Linear Fresnel Collectors. Figure 1
Schematic of a Fresnel collector with secondary reflector

size of the individual reflectors. This means the individual heliostats can be small but jointly cover a big aperture area. The drawback of heliostat systems is a lower optical efficiency per reflector area, mainly due to interference between individual reflector segments, which by principle can only approach the optical efficiency of an ideal (i.e., non-segmented) reflector geometry.

Whilst solar towers, dishes, and parabolic troughs were subject of continuous research and development during the past decades, it is only since late in the 1990s that linear Fresnel concepts are again on the agenda of a few companies and research groups worldwide.

Introduction

Linear Fresnel Collectors are named after Augustin Jean Fresnel (1788–1827), who among many other things developed refractive lenses, with the same focal length but using a fraction of the material compared to standard lenses. With Fresnel collectors the similar principle of segmenting the optical device is found but applied to a reflecting parabolic mirror rather than a refracting lens.

A first prototype linear Fresnel collector is documented from the Italian researcher Giovanni Francia in 1964 (see Fig. 2).

Linear Fresnel Collectors. Figure 2
Prototype linear Fresnel collector (From Giovanni Francia's (1911–1980) private archive)

Francia reported temperatures of 450°C and direct steam generation [1]. A few pilot installations from other groups followed in other parts of the world but none of them are known to be operated for a longer time. Technical problems with these projects are speculative. One might be the underestimation of the efforts to reach and maintain sufficient tracking precision.

At the end of the 1990s, two groups have restarted the development of linear Fresnel collector technology: the Australian Solar Heat and Power (SHP) (SHP was later renamed AUSRA, which was then acquired by the French AREVA Group) and the Belgian Solarmundo (Solarmundo was later transferred to Solar Power Group, which was joined by the German MAN Ferrostaal). A new company called Novatec Biosol (later renamed Novatec Solar and joined by the German ABB Group) entered the field in 2006 and could soon announce the first 1.4 MW linear Fresnel system to feed electricity into the electric grid (see Fig. 3).

The commercial rational behind linear Fresnel collectors compared to parabolic troughs for CSP applications is an expected advantage in cost reduction potential due to their simpler design, which shall compensate for their lower optical performance.

It is now the question whether the big CSP projects that are on their way will prove the commercial viability of the linear Fresnel collector technology.

A different market segment is addressed for the application of concentrating solar collectors in the field of industrial process heat. Here it can be necessary to mount the solar collectors on rooftops, which highlights the importance of low wind loads and high ground usage factors compared to the application in CSP projects. The company Industrial Solar GmbH already installed a number of such rooftop linear Fresnel systems, mostly for solar cooling applications but also for direct steam generation (see Fig. 4).

Linear Fresnel Collectors. Figure 3

Design of Linear Fresnel Reflectors

The general design idea is to cut a parabolic reflector into pieces, align the pieces horizontally and let them track the sun individually. When looking a little closer it becomes obvious that for an optimum design the reflector segments are not part of the same parabola but belong to parabolas with bigger focal lengths the farer off center the reflector segment is located (see Fig. 5).

Linear Fresnel Collectors. Figure 5
Ideal Fresnel reflectors for perpendicular irradiation

Linear Fresnel Collectors. Figure 6
Ideal Fresnel reflectors for off-normal incidence

Furthermore, the ideal shape of the heliostats changes when tracking the sun, because ideally they are different segments of different parabolas for different sun angles. The parabola segments are close to the optical axis for near normal reflection but far off-center for high reflectance angles. Ideally, each reflector should be able to take on the shape of segments of parabolas with different focal lengths and at a varying distance to the optical axis (see Fig. 6).

When practically constructing a linear Fresnel collector, one needs to compromise with the ideal geometrical design in order to stay within reasonable efforts for realization. It is, e.g., not reasonable to change the shape of reflectors for different inclinations. A fixed shape however will lead to an optical error called astigmatism for any incident angle other than the design angle. In other words, the cross-sectional focal point transforms to a focal area. This would happen anyway due to imperfections of material and assembly. The art of engineering is thus to find the optimum compromise of effort for construction and material and overall performance.

An interesting effect for the sun tracking principle is that for each heliostat the incremental tracking of mirrors is identical as long as the turning axis of the heliostat is in the reflecting plane (see Fig. 7). For practical use this means that with a simple mechanical coupling of neighboring mirrors it is possible to track a complete mirror field with only one actuator.

Linear Fresnel Collectors. Figure 7
For a change α of the incident angle each reflector has to be turned by α/2

Linear Fresnel Collectors. Figure 8
Aperture area $A = \Sigma A_i$ and gross area B of a Fresnel collector

Linear Fresnel Collectors. Figure 9
Cosine losses, shading, and blocking of neighboring reflectors

Reference Area

When discussing performances and efficiencies, it is important to define a reference area. For parabolic trough collectors, the reference area is defined as the projection of the reflector shape. It would be nice to find a similar definition for a linear Fresnel collector. However the projection of the reflector shape of a Fresnel reflector field changes with the incident angle so this definition would not be practical. A compromise was found by defining the aperture of a Fresnel collector as the projections of its reflectors when turned horizontally (see Fig. 8).

The typical optical performance of a Fresnel collector with respect to aperture area as defined above is lower than that of a parabolic trough with identical material parameters. This is not surprising given the approximate character of the Fresnel approach.

Optical losses are caused by the effect that the aperture area is not perpendicular to the incident rays and thus the active area is diminished by the cosine of the incident angle of each reflector. Structural shading by support structures and mutual shading and blocking of the reflectors are the other major optical loss factors (see Fig. 9).

The angular dependence of optical performance is described by the biaxial incident angle modifier (IAM). It is defined as the ratio of optical efficiency at a certain angle of incidence and the optical performance at perpendicular irradiation. Figure 10 gives a typical example of the incident angle modifier in longitudinal and transversal direction.

Receiver Design

The light absorbing receiver of a linear Fresnel collector is typically a selectively coated single steel tube or a bundle of steel tubes.

Many linear Fresnel collector designs use a secondary concentrator above a single receiver tube to reflect those rays to the back of the receiver tube that missed it in the first place. Non-imaging optics [2, 3] allow for an additional concentration via the secondary concentrator by a factor of approximately 2. In other words the target area of the receiver is enlarged, which reduces the requirements on optical precision of the primary reflectors.

Heat losses are reduced by enclosing the receiver in an insulating cavity with a transparent cover facing toward the primary reflectors. Alternatively, a vacuum tube similar to the receivers of parabolic trough collectors can be used.

Linear Fresnel Collectors. Figure 10
Incident angle modifier IAM

Benefits and Disadvantages

When discussing pros and cons of different collector technologies, it is important to differentiate between commercial and technical objectives. The following discussion shall look at technical specifics of Fresnel collectors, while presuming a reasonable commercial collector design.

With respect to parabolic trough collectors, the main features of a Fresnel collector are:

- Stationary receiver
  With a stationary receiver, there is no need for flexible hoses or ball joints to connect the receiver. Still the receiver ends will move due to thermal expansion. The maximum movement depends on the maximum operation temperature and the overall length of the receiver. This daily movement can easily be several meters, with a receiver length of many 100 m. However the respective compensators are standard industrial equipment.
- Illumination from underneath
  The receiver is always illuminated from underneath, no matter of the sun angle. This means that the thermal stress to the receiver does not change its direction throughout the day. In particular, there is no thermal stress that leads to a sideward bending of the receiver.
  The illumination from underneath is an important advantage for direct steam generation, at least for those flow patterns where the constant cooling of the upper part of the tube cannot be guaranteed (stratified flow or slug flow).
- Low wind load
  Low wind load is considered an advantage because it directly leads to slimmer and more lightweight mechanical structures, less influence by wind during operation, and fewer damages due to high wind speeds.
- High ground usage
  The optimum design of a Fresnel reflector carefully adjusts all geometrical parameters like height of the receiver, distances between the mirrors, the mirror size itself, the number of mirrors, etc. The resulting design typically has a higher thermal peak power per ground area compared to parabolic trough plants by a factor of approximately 1.5.
- Cleaning of mirrors
  This is one of the most important O&M factors for performance and cost. The basically flat primary mirrors and the possibility to position all primary reflectors horizontally offers the advantage of an easily accessible surface that can also be cleaned by robots with very little water consumption.

Of course also some disadvantages of Fresnel collectors need to be considered:

- Lower optical performance
  Shading/blocking of the primary reflectors lead to a reduced optical performance per aperture area.
- Higher tracking accuracy needed
  The movement of the reflected beam of a heliostat is twice the angular movement of the heliostat itself. This means that for the same concentration ratio a Fresnel reflector needs to be controlled twice as precisely as a trough and also the reflector shape needs to be accordingly more accurate.
- The yearly energy production per installed capacity is lower, which compensates partly the effect of a higher capacity per ground area.

In the end the above mentioned technical advantages translate into commercial benefits, which need to compensate the commercial drawbacks that result from technical disadvantages. It is thus a multidimensional

optimization procedure that finally leads to a highly competitive technology.

Future Directions

There are two target markets for linear Fresnel collector technology.

The presently most interesting market is the large-scale generation of electricity (CSP). Very large collector fields will generate steam to drive turbines in power blocks of many hundreds of MW power. Fresnel companies try to catch up with the prominence of trough technology in terms of operation experience and consequential bankability.

Most probably direct steam generation will be the predestined choice for linear Fresnel collectors but other heat transfer fluids are also worthwhile to be considered for this technology at least until latent or chemical heat storages are available in sufficient commercial scale to provide suitable storage for direct steam generation.

In areas with water scarcity it will be important to use low water consumption technologies, where the cleaning of the basically flat Fresnel mirrors seems advantageous for the implementation of automated cleaning devices.

The other target market is the provision of solar generated process heat in MW scale for industrial production processes and the generation of cold. Also small-scale power generation in Cogeneration or Polygeneration systems can be classified within this market of "industrial process heat" and will become more and more interesting in future.

Industrial process heat is still a much less developed market for solar technologies than CSP but it will eventually offer a substantial commercial potential.

The typical project size will be much smaller than in CSP projects, typically starting in the sub MW scale and up to several MW peak thermal capacities. Also other aspects might become predominant, e.g., the possibility of rooftop installation or the automated operation including the integration into hybrid fossil powered systems. Some of the above mentioned advantages of Fresnel collectors become even more interesting with rooftop applications (e.g., low wind load and high ground usage factor). Also the direct steam generation fits nicely to supplement the steam supply of industry.

Glossary

Interfacial impedance The resistance to lithium motion at the interface between the electrolyte and an electrode due to structure imposed on the electrolyte by the electrode, barriers to intercalation into the electrode, lithium desolvation energy, and/or the SEI layer.

Ionic liquid electrolyte An electrolyte comprised of a lithium salt dissolved in a room-temperature ionic liquid.

One-electron reduction The reduction of an electrolyte molecule by a single electron resulting in formation of species believed to be important contributors to the outer part of the SEI.

Organic liquid electrolyte An electrolyte comprised of a lithium salt dissolved in liquid carbonates, esters, ethers, or a mixture thereof.

Oxidative stability The ability of an electrolyte to remain electrochemically stable against oxidation at the surface of the cathode.

SEI layer The layer of electrolyte decomposition products that forms at the interface between an electrode (primarily the anode) and the electrolyte, called the solid electrolyte interphase or solid electrolyte interface. The SEI is believed to be comprised of an inner SEI layer and an outer SEI layer.

Solid polymer electrolyte An electrolyte comprised of a lithium salt dissolved in a polymer matrix.

Two-electron reduction The reduction of an electrolyte molecule by two electrons resulting in formation of species believed to be important contributors to the inner part of the SEI.

Definition of the Subject

Lithium batteries are complex devices whose performance optimization necessitates that they be well understood on multiple timescales and length scales, ranging from systems level to molecular. Optimization of the electrolyte, in particular, requires detailed, fundamental, molecular-level understanding of the chemical features that lead to stable electrolytes with large electrochemical windows – what electrolyte solvents and additives facilitate the formation of stable solid electrolyte interface layers and which features of the electrolyte result in good bulk and interfacial lithium transport properties as well as thermal stability, low-temperature transport, and low volatility/high safety [1, 2]. Molecular modeling has contributed significantly to this fundamental understanding of electrolyte properties and will continue to contribute to it in the future.

Introduction

Electrolytes and electrode/electrolyte interfaces are well suited for molecular modeling studies because important timescales and length scales are accessible to these powerful methodologies, and because gleaning molecular-level information from experiment is intrinsically challenging. While molecular modeling methods have not yet reached the point where they can be used exclusively in the design of electrolytes for improved battery performance, they have provided important insight into electrolyte stability, transport mechanisms, and the nature of the interface between the electrolyte and electrodes. These insights, or more precisely, a subset thereof, are the subject of this chapter.

The primary molecular modeling methods that have been extensively applied to lithium battery electrolytes and electrode/electrolyte interfaces are molecular orbital calculations and molecular dynamics simulations. The former involves ab initio and density functional methods and will be referred to quantum chemistry or QC calculations. In QC methods, atomic centers and electrons are treated explicitly and the optimized molecular orbitals (with corresponding energies and molecular/complex geometries) are obtained. QC methods are extremely powerful and accurate given adequate levels of theory (e.g., electron correlation treatment or density functional used) and adequate atomic basis sets, but quickly become computationally prohibitive with increasing system size. Hence, QC methods are applied to individual molecules or small clusters of molecules and as such do not typically allow for direct inclusion of condensed phase/solvent effects. Furthermore, while it is possible to perform molecular dynamics simulations using QC methods, the computational cost of this approach is such that the size of the system, the length of the trajectory, and the level of theory that can be employed are typically severely compromised. Despite their computational limitations, QC methods provide invaluable information relevant to the stability and performance of lithium battery electrolytes, including properties such as the electron affinity and ionization potential of a molecule or molecular cluster, solvation/complexation energies, and the energetics of various reactions. QC methods are also invaluable in providing information needed in the development of atomistic potential functions, or force fields, for molecular dynamics (MD) simulations.

MD simulations of electrolytes for lithium batteries retain the atomistic representation of the electrolyte molecules but do not treat electrons explicitly. Instead the influence of electrons on intermolecular interactions is subsumed into the description of the interatomic interactions that constitute the atomistic

potential or force field. The interatomic potential used in MD simulations is made up of dispersion/repulsion terms, Coulomb interactions described by partial atomic charges, and in some cases, dipole polarizability described by atom-based polarizabilities. The importance of explicit inclusion of polarization effects is considered below. In the most accurate force fields, interatomic potentials are informed by high-level QC calculations. Specifically, QC calculations provide molecular geometries, conformational energetic, binding energies, electrostatic potential distributions, and dipole polarizabilities that can be used to parameterize atomic force fields.

Because MD simulations use atomic force fields (i.e., do not explicitly include electrons), they are computationally orders of magnitude more efficient than QC methods. Hence, MD simulations can be run to predict bulk liquid properties, understand solvation/coordination structure, elucidate transport mechanisms, and study the interface between liquids and solid substrates, e.g., electrodes and electrolytes. Typical MD simulations involve hundreds of molecules and thousands of atoms, and trajectories of many nanoseconds can be routinely generated. Unlike QC methods, however, most classical MD simulation methodologies do not allow for chemical reactions, specifically the making and breaking of covalent bonds. An exception is MD simulations that involve reactive force fields, such as the ReaxFF, that allow for bond breaking and formation through use of bond order potentials and partial atomic charges that depend upon the bonding environment of an atom. Reactive force fields are computationally more expensive than nonreactive atomistic force fields, resulting in typically smaller simulation systems and shorter trajectories. Furthermore, reactive force fields, in an effort to minimize complexity and number of parameters, are less accurate in the prediction of thermophysical and transport properties than the better nonreactive force fields.

Quantum Chemistry Studies of Oxidative Stability of Electrolyte Compounds

Electrolyte oxidative stability is one of the key parameters for designing electrolytes compatible with a cathode. An electrolyte should be either anodically stable toward the cathode or form a stable passivation layer on the cathode that is capable of conducting lithium ions and accommodating electrode dimensional changes during cycling. QC calculations were used to estimate the oxidative stability of electrolyte solvents [3, 4], additives [5], anions [6–8], and redox shuttle molecules [9]. A free-energy cycle shown in Fig. 1 is used to relate the gas-phase adiabatic ionization potential (IP) to the absolute oxidation potential using the free energy of solvation $\Delta G^0{}_S(M)$ and $\Delta G^0{}_S(M^+)$ for the reduced and oxidized forms of a molecule M. IP is defined as the enthalpy changes of the oxidation reaction in the gas phase at 298 K. QC calculations yield the standard oxidative potential $E^0{}_{abs}(M)$ at the absolute electrochemical scale [10, 11] with the reference vacuum state corresponding to an electron at rest in a field-free vacuum.

Using the free-energy cycle shown in Fig. 1, $E^0{}_{abs}(M)$ is expressed by Eq. 1

$$E^0{}_{abs}(M) = IP + \left[-T\Delta S + \Delta G^0{}_s(M^+) - \Delta G^0{}_s(M)\right]/F \quad (1)$$

where F is Faraday constant 23.061 kcal per volt gram equivalent and $-T\Delta S$ is the entropy difference in the gas phase between M and M^+. Most electrochemical experiments, however, report oxidation potential versus standard hydrogen electrode (SHE) or Li^+/Li in the lithium battery literature instead of using absolute oxidation potential. The SHE at room temperature (25°C) is estimated [11] to have the absolute potential of 4.42 V in aqueous solutions. Older International Union of Pure and Applied Chemistry (IUPAC) recommendation [10] of 4.44 V is often used. The IUPAC recommended values for the absolute SHE potential in nonaqueous solvents are within a few tens of volts of

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 1 Free-energy cycle for the redox reaction $M \rightarrow M^+ + e^-$, $M_{(g)}$ denotes molecule M in gas phase, while $M_{(S)}$ denotes the solvated molecule

the value of the absolute SHE potential in aqueous solutions. For example, it was recommended by IUPAC to use the following absolute potential values for SHE in nonaqueous solvents: 4.13 ± 0.06 V for acetone and 4.60 ± 0.10 for acetonitrile. The Li^+/Li standard absolute electrode potential is −3.04 V versus SHE. Most commonly [4, 5, 7, 9], the aqueous value of 4.44 – 3.04 = 1.4 V is used to convert from the absolute electrochemical scale used in QC calculations to the experimentally measured potential versus Li^+/Li.

An extensive QC study [4] of 160 structurally unrelated organic molecules reported prediction of IPs with a standard deviation of 0.14 V at B3LYP/6-311++G (2df,2p)//B3LYP/6-31+G(d). Such good agreement was achieved after correcting IPs obtained from QC calculations for the systematic underestimation of the experimental data by adding 0.28 V to all QC IP values. At the next step, $E^0_{abs}(M)$ was calculated from IP using Eq. 1. Widely available in QC codes, polarized continuum models (PCM) are commonly used to estimate free energy of solvation of the reduced and oxidized forms of M (see Eq. 1 and Fig. 1). The standard redox potentials of 270 structurally unrelated organic molecules in acetonitrile were predicted with the standard deviation from experiments of 0.17 V [4]. This accuracy is sufficient for guiding the electrolyte solvent development. One caveat, however, should be mentioned. For a number of alkene molecules, the deviation between the experiment and the theory was about 0.5–0.8 V (i.e., 11–18 kcal/mol). No explanation was given for this discrepancy [4].

The other QC studies [5, 9] focused on the redox additives that could be reversibly reduced and oxidized for the overcharge protection. The calculated oxidative potential using B3PW91/6-31 + G(d,p) density functional theory (DFT) level were found in close agreement with the experimental data with the root mean-square deviation is 0.08 V and the maximum deviation is 0.15 V, indicating high fidelity of QC calculations of the solvent oxidation potential using PCMs to account for the solvation effects [5]. The experimental measurements were performed in 1 M lithium hexafluorophosphate ($LiPF_6$) ethylene carbonate (EC)/ethylmethyl carbonate (EMC) (1/2, v/v) supporting electrolyte on Pt wire. The correlation coefficients (R^2) of IP(calc. QC), E_{ox}(calc. QC) with respect to E_{ox}(exp.) were 0.84 and 0.98, respectively. Similarly, Wang, Buhrmester, and Dahn [9] reported an excellent agreement between the calculated values for 17 redox shuttle additives with the root-mean-square deviation between the calculated and measured oxidation potentials being 0.15 V with the maximum deviation of 0.25 V, indicating that DFT calculations at B3LYP/6-31 G(d,p) could be effectively used for screening redox additives.

Comparison of the common electrolyte solvents (EC, propylene carbonate [PC], dimethyl carbonate [DMC], EMC, vinylene carbonate [VC], dimethoxyethane [DME]) oxidative stability with experiments was reported by Zhang et al. [3]. While trends of the oxidative stability were reasonably captured in this study, typical deviations between experiments and simulations were reported to be around 0.5–1.0 V. Note that Zhang et al. [3] did not use the value of 1.4 V to convert from the absolute to Li^+/Li potential scale, instead they used the Li/Li^+ and M/M^+ cycles with a number of calculated/estimated quantities, resulting in the absolute potential versus Li^+/Li being around 2.2 V. Application of the value of 1.4 or 1.54 V derived from SHE potential in water and acetonitrile and using the standard Li^+/Li vs. SHE potential will result in an improved agreement between QC-based values reported by Zhang et al. [3] and experiments.

Ue et al. [6] and Johansson [7, 8] have reported anion oxidative potentials. They found a significant correlation between the predicted single molecule gas-phase QC values and experimental oxidation potential measurements performed on numerous solvents and salt concentrations. Figure 2 and Table 1 shows the vertical (e.g., anion (charge=−1e) geometry was used in the oxidized molecule (charge = 0) energy calculation) ionization energy (ΔE_v) and free energy of anion ionization (ΔG_v) from the Johansson work [8] that employed VSXC DFT functional and 6-311 + G (2df,p) basis set. Johansson [8] used vertical instead of adiabatic energies in calculations to lower the computational cost. QC calculations generally reproduced the order of oxidation potentials with the exceptions of the large anions that have low oxidative stability where deviations up to a few volts were observed. Another case where QC calculations fail to reproduce oxidative potential trends was the comparison of highest occupied molecular orbital (HOMO) calculations and measured oxidative potential of propargyl methanesulfonate (PMS) and EC [12]. Calculations indicated higher HOMO absolute value implying higher oxidative

stability of EC compared to PMS by 0.8–1.0 V, while oxidative stability of PMS on Pt was higher compared to EC by ~0.2 V in the $LiPF_6$-based electrolytes [12]. It is important to note that anodic stability of electrolytes on active cathode surfaces could be significantly (up to a few volts) lower than the electrolyte stability on Pt or glassy carbon; therefore, one would need to include surfaces in the electrolyte calculations in order predict oxidative stability of electrolytes on active materials [1].

While the focus of this section was on the prediction of oxidation potentials, reduction potentials of EC, PC, DMC, VC, and vinylethylene carbonate (VEC) were calculated using quantum chemistry methods and compared with experiments [13–15].

Modeling of Reductive Decomposition of Electrolytes

The properties of the solid-electrolyte interface (SEI) that forms as a result of reduction of the electrolyte solvent and lithium salt are key elements in determining the performance of lithium ion batteries [1, 16]. The electrolyte solvent is typically comprised of a mixture of linear and cyclic carbonates, with EC being a major component of most electrolytes. The solvent and lithium salt anion undergo one- and two-electron reduction at the anode, typically Li-intercalated graphite. During the first cycle, the reaction products of electrolyte reduction form a thin SEI film, which in the ideal case protects the electrolyte from further reductive decomposition during subsequent cycles while at the same time contributing significantly to the resistance for Li^+ exchange between the electrolyte and the electrode. There have been number of experimental studies focusing on understanding of mechanisms of the SEI formation, a detail discussion of which can be found in Ref. [1, 17]. In general, the SEI is thought to consist of an inner and an outer layer. The inner layer is believed to be primarily comprised of doubly (two electron) reduced compounds, such as Li_2CO_3, while the outer SEI layer is thought to be comprised largely of reaction products of singly (one electron) reduced electrolyte species [1, 18–21], the nature of which remains controversial.

Given the importance of the SEI layer in lithium batteries, it is clear that improved understanding of the mechanisms of electrolyte decomposition and the formation of the SEI layer would facilitate optimization of battery performance. The reductive decomposition of organic solvents at the anode–electrolyte interface is largely responsible for the formation of the SEI. The electrochemical reactions leading to the formation of the SEI are complex and not well understood. Fortunately both QC and molecular dynamics simulations have provided some insight into reaction pathways that are believed to be important in the formation of the SEI. Reduction pathways for EC [14, 15, 22–24], PC [15, 23, 25], and VC [15, 23, 24], among others, have been most extensively studied extensively computationally, with the greatest focus on EC. Two schemes have been proposed in the literature for reductive decomposition of solvents at the anode interface. The first involves decomposition after electron transfer to Li^+-solvent complexes, while the latter involves direct decomposition on the electrode surface. Computational insights into both of these schemes for EC are considered below.

Reduction of Li^+–EC Complexes

One-Electron Reduction of EC The most important component of the current generation of electrolytes is EC. The initial step in the commonly accepted single-electron reduction mechanism is shown in Fig. 3a. QC calculations [14] have shown that this reaction is energetically unfavorable in the gas phase and energetically favorable when solvent effects are taken into account through the polarized continuum model approach. However, the reaction becomes dramatically more favorable when Li^+ is complexed to the carbonate molecule, resulting in the cation/anion complex shown in Fig. 3b. The next step in the one-electron reduction process is commonly believed to be the opening of the closed EC radical anion (complexed to Li^+), denoted as c-EC$^-$, to form an open radical, shown in Fig. 3c. This process involves a substantial energy barrier leading ultimately to a substantially lower energy radical anion [14].

The fate of the o-EC$^-$ radical anion formed from one-electron reduction of EC is a matter of central importance in understanding the formation of the SEI in EC-based electrolytes, and is a matter of controversy. Dilithium ethylene dicarbonate $(CH_2OCO_2Li)_2$ has been proposed as a major component of the outer SEI layer [1], resulting from combination reactions of pairs of o-EC$^-$, as shown in Scheme I in Fig. 4. Fourier transform infrared (FTIR) and x-ray photoelectron spectroscopy (XPS) studies of SEI films formed on lithium metal in EC-based electrolytes reveal the presence of alkyl carbonates [19, 26], while FTIR shows the presence of alkyl carbonates in the SEI formed from EC/diethyl carbonate electrolytes on graphite [20]. Hydrolysis of alkyl carbonate species formed from reduction of EC on noble metal electrolytes leads to the formation of ethylene glycol, which has been taken as evidence for the formation of $(CH_2OCO_2Li)_2$ [27]. Nuclear magnetic resonance (NMR) studies of the surface species formed on graphite in EC electrolytes resulted in spectra consist with that of alkyl carbonates, and in particular, the spectrum of $(CH_2OCO_2Li)_2$ [28]. A combined transmission electron microscopy (TEM)/FTIR study of the SEI formed on graphite in a EC/lithium perchlorate ($LiClO_4$) electrolyte revealed the formation of alkyl carbonates, one of whose chemical composition (O/C ratio = 1.5) is consistent with $(CH_2OCO_2Li)_2$ [29].

In addition to experimental investigations, QC studies have provided important insight into single reduction reactions of EC. In one study, DFT studies at B3PW91/6-311++G(d,p) level of theory were performed in order to investigate the energetics of

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 3 (**a**) Reduction of EC by one electron to form the closed radical anion c-EC$^-$; (**b**) Li^+/c-EC$^-$ complex; (**c**) Li^+/c-EC$^-$ complex

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 4 Proposed reaction schemes involving singly reduced EC

radical termination reactions of EC^- [14]. Both $(CH_2OCO_2Li)_2$ and dilithium butylene dicarbonate $(CH_2CH_2OCO_2Li)_2$ (Scheme II, Fig. 4) are believed to form by the reaction of two o-EC^-, while an ester-carbonate compound forms from the reaction of o-EC^- with c-EC^- as shown in Fig. 4 Scheme III. In terms of energy and free energy, $(CH_2CH_2OCO_2Li)_2 < (CH_2OCO_2Li)_2 + CH_2 = CH_2 <$ ester-carbonate compound [14]. Furthermore, the DFT study revealed that while Li^+/o-EC^- is much lower in energy than Li^+/c-EC^- (by about 27 kcal/mol), there is a substantial energy barrier for opening c-EC^- to form o-EC^-, around 13 kcal/mol in energy and 11–12 kcal/mol in free energy. For the elementary reaction $A \leftrightarrow A^*$, where A^* represents an activated complex, the Eyring rate equation is given as [30]

$$k = \frac{k_b T}{h} \exp\left[-\frac{\Delta G^*}{k_b T}\right] \tag{2}$$

At room temperature, the estimated lifetime c-EC^-, given as $1/k$, is around 100 μs. Hence, reactions involving the high-energy but long-lived c-EC^- form of the EC radical anion to form the ester-carbonate compound shown in Fig. 4 should be considered as a possible contributor to the outer SEI in EC-based electrolytes.

While the presence of $(CH_2OCO_2Li)_2$ in the SEI formed from EC-based electrolytes is not disputed, there is limited evidence for the presence of $(CH_2CH_2OCO_2Li)_2$ and the ester-carbonate compound. The combined TEM/FTIR study that claimed evidence for the presence of $(CH_2OCO_2Li)_2$ also found evidence for an alkyl carbonate compound with O/C ratio = 1, which the investigators associated with $(CH_2CH_2OCO_2Li)_2$ [29]. This O/C ratio is also consistent with the ester-carbonate compound. However, in their NMR analysis of surface compounds that was consistent with the presence of $(CH_2OCO_2Li)_2$, Xu et al. ruled out the possibility of these compounds [28]. In general, however, studies (e.g., FTIR and XPS) that reveal the presence of alkyl carbonates in the SEI formed in EC-based electrolytes do not allow for the differentiation between $(CH_2OCO_2Li)_2$ and $(CH_2CH_2OCO_2Li)_2$ and the ester-carbonate compound.

In addition to QC studies, reactive molecular dynamics (RMD) simulations using the reactive force field ReaxFF have been used to gain insight into reactions of singly reduced EC in the condensed (solution) phase [31]. In this study the reaction of Li^+/o-EC^- with both Li^+/o-EC^- and Li^+/c-EC^- has been studied in a solution of EC molecules. A snapshot of the system

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 5 Snapshot of a reactive molecular dynamics simulation (ReaxFF) of singly reduced EC species in a solution of EC molecules [31]

is shown in Fig. 5. RMD simulations were used to determine the free energy as a function of reaction coordinate (see below) and to examine the propensity of various radical combination reactions to occur in the condensed phase of an EC solvent.

The free energy in the condensed phase was determined for the reactions of Li^+/o-EC^- with Li^+/o-EC^- according to Scheme I and Scheme II in Fig. 4. ReaxFF simulations predict essentially no barrier for formation of $(CH_2CH_2OCO_2Li)_2$ while a barrier of around 12 kcal/mol is seen for the formation of $(CH_2OCO_2Li)_2 + CH_2 = CH_2$. ReaxFF simulations also predict $(CH_2CH_2OCO_2Li)_2$ to be of lower energy than $(CH_2OCO_2Li)_2 + CH_2 = CH_2$, in qualitative agreement with ab initio predictions [14]. The only reaction observed in an o-EC^-/EC system containing many Li^+/o-EC^- complexes was the rapid combination of o-EC^- radical pairs to form $(CH_2CH_2OCO_2Li)_2$ (Scheme II, Fig. 4). No formation of $(CH_2OCO_2Li)_2 + CH_2 = CH_2$ was observed in simulations of o-EC^-/EC system, indicating the presence of an appreciable barrier to this reaction.

The free energy of the condensed phase reaction path for Li^+/o-EC^- with Li^+/c-EC^-, Scheme III, Fig. 4, as a function of the reaction coordinate (C-O distance) reveals a barrier for this reaction of around 6 kcal/mol, but it is significantly less than that for ring opening reaction as estimated from QC of 11–12 kcal/mol [14]. This barrier is sufficiently large such that no reactions were observed in simulations of the o-EC^-/c-EC^-/EC system at 313 K. At elevated temperature (500 K), the reaction shown in Scheme III, Fig. 4, was observed in ReaxFF simulations on the timescale of a hundred picoseconds. At this temperature, the estimated lifetime (mean time to ring opening) of c-EC^- is, according to Eq. 2, much greater, around 10 ns. At lower temperatures, the separation in timescale between the reaction of Li^+/o-EC^- with Li^+/c-EC^- and the ring opening reaction will become even greater due to the much higher activation energy for the latter reaction. These results imply that the reaction of Li^+/o-EC^- with Li^+/c-EC^- occurs rapidly enough that this reaction could be important in the formation of the outer SEI in EC-based electrolytes.

In summary, a review of experimental and QC studies of compounds present or likely to be present in the outer SEI formed at the anode in EC-based electrolytes leads to the conclusion that these studies cannot be easily reconciled regarding the importance/presence of $(CH_2CH_2OCO_2Li)_2$, $(CH_2OCO_2Li)_2$, and the ester-carbonate compound. Condensed phase ReaxFF simulations have demonstrated that while $(CH_2CH_2OCO_2Li)_2$ and the ester-carbonate compound can easily form through the mechanisms shown in Fig. 4, $(CH_2OCO_2Li)_2$, often suggested as the most important compound of the outer SEI, does not form through the commonly held mechanism of combination of two o-EC^- radicals (Scheme I, Fig. 4). Furthermore, the large barrier for the ring opening reaction leading to formation of o-EC^- from c-EC^-, revealed by previous QC studies, combined with the relatively low barrier for formation of the ester-carbonate compound from reaction of c-EC^- with o-EC^- implies that the presence of the ester-carbonate compound as a component of the SEI in EC-based electrolytes should be given serious consideration. Furthermore, reactions of the relatively long-lived c-EC^- with electrolyte additives such as VC may also be important.

Two-Electron Reduction of EC In addition to participating in the formation of the outer SEI through one-electron reduction, EC can undergo two-electron reduction. The resulting compounds are believed to be

important components of the inner part of the SEI. QC reveals that this is a two-step process involving one-electron reduction to the o-EC radical followed by reduction by the second electron [14]. QC reveals that this an energetically unfavorable reaction in the gas phase but energetically favorable in the presence of Li^+, resulting in the formation of ethylene gas and $LiCO_3^-$. This doubly reduced form of EC can react with an additional Li^+ form lithium carbonate (Li_2CO_3) or with a Li^+/EC complex to form dilithium ethylene dicarbonate, also shown in Fig. 4. Both of these compounds are believed to be present in the inner SEI [16, 32, 33].

Decomposition at Electrode Surfaces Computational investigation of the reduction of carbonate compounds occurring directly on the anode (e.g., lithium metal) surface has received less attention than reactions in the gas phase or bulk electrolyte. In one example, a QC study of a number of important electrolyte compounds, including EC, reacting with lithium clusters, has been conducted [14]. While the level of theory is modest, qualitative trends were clear. Reaction of EC with the lithium cluster results in the formation of ethylene plus Li_2CO_3, a known major component of the inner SEI. The energetics of this reaction is highly favorable, while there was found to be an appreciable activation energy for the reaction. This high activation energy is somewhat surprising due to the known reactivity of lithium metal with carbonate solvents, and may reflect the computational approach and modest level of theory employed. ReaxFF simulations of EC in contact with lithium metal show fast reaction on a timescale of picoseconds (ps) resulting in formation primarily of Li_2CO_3 and ethylene gas [31]. These initial RMD simulations on lithium metal show no signs of formation of dicarbonate compounds or the presence of an appreciable barrier for the formation of Li_2CO_3.

The decomposition of EC on graphitic anode with C = O, C–OH, and C–H terminations was studied at 450 K in ab initio simulations using the Perdew–Burke–Ernzerhof (PBE) functional, with a more accurate PBE0 functional used as for spot checks [34]. Fast EC decomposition on ps timescale occurred upon two-electron reduction at the graphite edge rich in oxidized sites (C = O and C-OH), yielding CO_3^{2-} and $OC_2H_4O^{2-}$. A potential reaction between $OC_2H_4O^{2-}$, or HOC_2H_4OH in the proton rich environment, with CO_2 or CO_3^{2-} was suggested as a possible route to forming $(CH_2CO_2Li)_2$ SEI product but was not observed presumably because of short simulation timescales [34]. The C = O termination was significantly more active in decomposing EC than C–H termination.

Molecular Dynamics Simulations of Bulk Electrolyte Properties

Organic Liquid Electrolytes

Molecular dynamics simulations were used to study a number of electrolytes with potential interest to lithium battery applications: EC:DMC/$LiPF_6$[35], EC/LiTFSI [36, 37], DMC/LiTFSI [38], GBL/LiTFSI [38], oligoethers/Li salts [39–41], acetamide/LiTFSI [42], EC/$LiBF_4$ [43], PC/$LiBF_4$ [43, 44], PC/$LiPF_6$ [44], DMC/$LiBF_4$ [43], oligoethers/$LiPF_6$ [45–47], and PC/LiTFSI [37]. The lithium cation coordination by solvent molecules, cation–anion aggregation, and transport properties were derived from MD simulations. It is important to pay attention to the reported simulation time because some of the earlier simulations by Li et al. [48] and Soeten [43] were only 200 ps and 100 ps long [43, 48], which is less than one EC-lithium residence time (~0.5 ns) [35] and significantly less than the lithium–anion residence time of 2–3 ns found for similar electrolytes at 298 K [35]. Experience indicates that MD simulation trajectories should be longer than the cation–anion or lithium-solvent residence time in order to obtain an equilibrated ion aggregation and the composition of the ion solvation shell. Recent MD simulations [35, 38] were performed for 7–20 ns to ensure a complete equilibration and extraction of the accurate conductivity values.

Early study of one $LiBF_4$ in PC, EC, and DMC by Soeten [43] provided initial insight into the structure of the lithium solvation shell. Four strongly bound solvent molecules in a tetrahedral arrangement around lithium cation were reported [43], which is qualitatively consistent with the recent MD studies [35, 36, 38] and ab initio simulations of Li^+ in 32 EC [34]. MD simulations with polarizable force fields predicted ion diffusion coefficients [35, 36, 38, 49] within 40% of experiments for DMC/LiTFSI, EC/LiTFSI, PC/LiTFSI,

DMC/LiTFSI, (EO_n)/LiTFSI, where EO is ethylene oxide repeat unit, $n = 2,5,12$ and EC:DMC/$LiPF_6$. MD simulations employing nonpolarizable force field [37], on the other hand, predicted ion diffusion a factor of 2–4 slower for EC/LiTFSI and PC/LiTFSI and 5–7 times slower for PC/$LiBF_4$ and PC/$LiPF_6$ [44]. Conductivity was predicted a factor of 5 lower for PC/$LiPF_6$ [50] and a factor of 2 lower for PC/LiTFSI [37] and EC/LiTFSI [37] in MD simulations using nonpolarizable force fields. MD simulations using polarizable force fields predicted electrolyte conductivity within 20–40%. Figure 6 shows conductivity of EC: DMC/$LiPF_6$ as a function of solvent composition and temperature. MD simulations slightly overestimate EC/$LiPF_6$ conductivity but overall quality of the conductivity predictions is satisfactory, especially in light of recent results from the Umebayashi group [44] that reported conductivity of PC/$LiPF_6$ and PC/$LiBF_4$ from MD simulations being a factor of 5–7 lower than experiments.

Many of the practical electrolytes contain a combination of linear and cyclic carbonates doped with $LiPF_6$ salt. Using $LiPF_6$ salt yields electrolytes with high ion dissociation, conductivity and aluminum current collector passivation and SEI formation [1, 2]. EC has high melting point of 36.4°C, a high dielectric constant ($\varepsilon \approx 90$), and an acceptable viscosity (1.9 cP at 40°C) [1]. Its ability to dissociate lithium salts is attributed to its high dielectric constant [1]. The addition of lower viscosity and lower dielectric constant ($\varepsilon \approx 3.1$) to linear carbonate solvents such as DMC decreases electrolyte viscosity, reduces its melting point, and improves conductivity. While EC dissolves lithium salts much better than DMC presumably due to high dielectric constant (90 for EC versus 3 for DMC), the question remains as to the number of EC and DMC molecules contributing to the lithium solvation shell in the mixed EC:DMC electrolyte. Intuitively, one expects EC contribution to dominate over DMC because of the difference in dielectric constants [1]. The issue of the competitive lithium cation solvation in mixed linear and cyclic carbonate solvents was addressed in a recent MD simulation and QC study [35]. Both EC and DMC were found to participate in the Li^+ solvation in mixed EC:DMC (1:1) electrolytes despite a huge difference between their dielectric constants (90 for EC versus 3 for DMC). These results were found in agreement with the reanalyzed [53] Raman spectroscopy experiments. A more detailed examination of the mixed electrolyte MD data revealed that the free lithium cations slightly favor EC solvation, while Li^+ contact ion pairs with PF_6^- anions leads to a preference for DMC in the Li^+ solvation shell. These conclusions are in accord with the quantum chemistry studies that indicated that $LiPF_6$ ion pair binds slightly stronger to DMC compared to EC, while binding energy of Li^+-EC is larger than Li^+-DMC. Analysis of the lithium cation

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 6 Solvent composition (*left*) and temperature (*right*) dependence of ion conductivity from MD simulations [35] and experiments [51, 52]. Solvent: Li ratios were the following: EC:Li = 13, DMC:Li = 10, (EC + DMC): Li =11.8 for EC:DMC mol/mol = 1/1 and (EC + DMC): Li =10.7 for EC:DMC mol/mol = 3/7

coordinated by four solvent molecules (EC and DMC as shown in Fig. 7) indicated that the most stable configuration is not $Li^+(EC)_4$, but $Li^+(EC_3, DMC)$ and energy of the $Li^+(EC_2, DMC_2)$ cluster is only 0.8–1.6 kcal/mol higher than $Li^+(EC_3, DMC)$ depending on the level of theory used.

MD simulations offer a unique opportunity to investigate the degree of ion correlation from both structural and dynamic points of view. The degree of ion dissociation α_s (static) defined as the fraction of Li^+ and PF_6^- with no counterion in their first solvation shell, i.e., r(Li-P) < 4.4 Å for all pairs, is shown in Fig. 8. The fraction of free ions increases near linearly with increasing EC fraction in electrolyte and that increasing temperature slightly decreases the fraction of free ions. Surprisingly, the DMC/$LiPF_6$ 1 M electrolyte, which exhibits a reasonable DC conductivity shown in Fig. 6, has a very low fraction of free ions (1.7% at 298 K). The degree of dynamic correlation (α_d) was extracted from MD simulations using ion self-diffusion

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 7 Geometry of the three most stable clusters of Li^{4+} coordinated by EC and DMC solvent molecules from M05-2X/6-31 G* geometry optimization

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 8 The dynamics (α_d) and static (α_s) degree of ion dissociation (fraction of free ions) for EC:DMC/$LiPF_6$ at 298 K at an ~1 M salt concentration

coefficients and conductivity (λ) as given by Eqs. 3–4 in order to compare with α_s (static),

$$\alpha_d = \frac{\lambda}{\lambda^{N-E}} \tag{3}$$

$$\lambda^{N-E} = \frac{e^2}{Vk_BT}(n_+D_+ + n_-D_-) \tag{4}$$

k_B is the Boltzmann constant, T is temperature, V is the volume of the simulation box, and D_- and D_+ are self-diffusion coefficients of the anion and cation, respectively. The degree of ion dynamic correlation α_d is plotted versus electrolyte composition and temperature in Figure 8 together with the static fraction of free ions from the structural analysis α_s. It was found that α_d is always higher than the fraction of free ions from the structural analysis (α_s), indicating an important contribution from the charged ion clusters transport to ion conductivity discussed in details elsewhere [35]. Joint pulsed gradient spin echo (pgse)-NMR and conductivity analysis of LiTFSI in multiple electrolytes at solvent:Li ratio of 20 at 298 K for PC/LiTFSI and DMC/LiTFSI yielded α_d values 0.62 and 0.11 in accord with MD predictions for EC:DMC/$LiPF_6$ shown in Fig. 8 provided $LiPF_6$ and LiTFSI yield similar α_d [54]. This indeed seems to be the case as similar α_d were found for LiTFSI and $LiPF_6$ salts in γ-butyrolactone (GBL) electrolyte from a combination of pgse-NMR and conductivity analysis [55].

Analysis of the solvent residence times relative to the diffusion coefficients allows one to estimate the frequency of the solvent exchange during the time it takes for a solvent to diffuse its own size [49]. For EC:DMC/$LiPF_6$ electrolytes [49], an approximately equal contribution from vehicular motion with the first solvation shell and solvent exchange for Li solvated by EC was found. In contract to the lithium motion in carbonates, in oligoethers, Li^+ moves 3–4 solvent molecules before its solvation shell is renewed, indicating that motion or the Li^+ together with its solvation shell dominates over solvent exchange mode of the lithium transport in oligoethers.

Polymeric Electrolytes

Solid polymer electrolytes (SPEs) are formed by doping a polymer with a lithium salt. SPEs have several advantages over traditional organic solvent–based electrolytes that include negligible volatility, leading to increased safety and reduced environmental impact, and intrinsic mechanical integrity, which could eliminate the need for a separator [56]. However, SPEs suffer from a major disadvantage, namely, dramatically reduced lithium ion conductivity compared to organic solvent-based electrolytes. Consequently, SPEs can currently only be employed at elevated temperatures, typically 60–80°C [56]. Simulation and modeling studies of SPEs have concentrated on elucidating the mechanism of ion motion in SPEs, and in understanding how polymer structure influences ion motion.

Polyethylene oxide (PEO)-based polymers have been investigated most extensively as SPEs both experimentally [56] and in simulations [40, 57–67]. These polymers are very effective at dissolving lithium salts due to strong Li^+-ether oxygen binding. QC [68] and MD simulation studies [58] of oligoethers (low molecular weight PEO) as well as PEO have revealed that Li^+ cations are very strongly coordinated by an average of 5–6 ether oxygen atoms in configurations similar to that shown in Fig. 9. Simulations reveal that coordination of Li^+ usually involves a single oligoether or two segments of a single PEO chain as shown in Fig. 9 [58].

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 9
A representative configuration of Li^+ cation coordination by an oligoether chain from MD simulations

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 10
Ion diffusion in (**a**) pentaglyme (EO_5DME) and (**b**) oligoethers from MD simulations [49] and pulsed field gradient (pfg)-NMR experiments [69]

The nature of ether-Li^+ binding has a very strong influence on the mechanism for Li^+ conduction in PEO-based SPEs. This can be understood by first comparing the mechanism of Li^+ diffusion in an oligoether versus that in organic solvents. As discussed in Organic Liquid Electrolytes, Li^+ motion in organic liquid electrolytes occurs by a mixture of vehicular (with solvent shell) and structural (exchange of solvent shell) diffusion [49]. In contrast, simulations reveal that Li^+ diffusion in pentaglyme (six repeat unit PEO) + LiTFSI, compared with experiment in Fig. 10, occurs almost entirely by a vehicular mechanism [49]. In other words, a pentaglyme/Li^+ complex diffuses on average distances many times larger than the size of the pentaglyme before Li^+ changes complexation to a different pentaglyme molecule. The residence time of Li^+ with a pentaglyme molecule is around 50 ns, compared to around 1 ns in propylene carbonate [49].

While the lack of an efficient structural diffusion mechanism has relatively little influence on Li^+ motion in pentaglyme because of the fast center-of-mass diffusion of pentaglyme, the situation is quite different in higher molecular weight PEO. Because the center-of-mass diffusion of PEO is negligible, a Li^+ cation

necessarily *must* change coordinating PEO chains, i.e., undergo "jumps" between PEO chains, in order to move distances greater than the size of the PEO chain. Figure 11a shows ion and polymer diffusion in a PEO-LiTFSI SPE as a function of inverse temperature from simulation and experiment [38], while Fig. 11b shows conductivity as a function of salt concentration [58]. In both cases, excellent agreement between simulation and experiment can be seen. Compared with pentaglyme (Fig. 10), it can be seen that Li^+ transport is considerably slower in the SPE, while the diffusion of TFSI is reduced relatively little, indicative of the relative independence of TFSI motion from that of the solvent/polymer. This leads to a significantly lower transference number in the SPE compared to the liquid electrolyte as a significantly greater fraction of charge is carried by TFSI in the former due to the very slow Li^+ motion. Furthermore, while pentaglyme motion is faster than that of Li^+ in the oligoether electrolyte, PEO center-of-mass motion is considerably slower than that of cation, supporting the supposition that the vehicular mechanism, which is so important in the oligoether, does not contribute significantly to Li^+ in the SPE. Note that Li^+ motion in the PEO SPE can be well reproduced by a model that allows for 1-D diffusion along Gaussian chains, motion with a segment of the chain with occasional interchain jumps [59, 66].

Coupling of Ion Motion and Polymer Segmental Motion Figure 12 shows the dependence of Li^+ and $TFSI^-$ motion on salt concentration from both experiment and simulation [58]. Also shown is the time (relative to that at for Li:EO = 0.05) from simulations at which the mean-square displacement of the ether oxygen atoms reaches 50 $Å^2$, the length scale of the cage imposed by neighbor packing. This timescale is directly related to the timescale of conformational transitions. Figure 12 reveals that while TFSI motion remains much faster than that of Li^+ for all salt concentrations, the translational dynamics of both ions follow the same dependence on salt concentration as polymer segmental/conformational dynamics, i.e., a dramatic decrease in mobility with increasing salt concentration. These results show that both cation and anion dynamics are strongly coupled with local polymer relaxation. The slowing of segmental/conformational dynamics of the polymer with increasing salt concentration is due to the strong binding between ether oxygen atoms and Li^+, which greatly restricts conformational motion. The correlation of both cation and anion dynamics with local polymer relaxation is further illustrated by simulations in which the barrier for dihedral/conformational transitions were artificially increased by 1.3 kcal/mol [58]. Simulations of the PEO/LiTFSI SPE at EO:Li = 20:1 at 393 K revealed a decrease in the diffusion coefficient of both $TFSI^-$ and

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 11 (**a**) Diffusion in a PEO/LiTFSI electrolyte from simulation and experiment. (**b**) Ionic conductivity in a PEO/LiTFSI electrolyte from simulation and experiment

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 12 Dependence of Li^+ and $TFSI^-$ motion on salt concentration from both experiment and simulation

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 13 Structure of comb-branch copolymers used as SPEs

Li^+ by a factor of 3, and an increase in the polymer segmental relaxation time by about the same factor.

An interesting feature of the PEO SPE is the maximum in conductivity for Li:EO ratio around 0.05, as can be seen in Fig. 11b. Simulations reveal that this is due to two counter effects. On the one hand, ionic conductivity increases with increasing salt concentration due to the increase in the number of charge carriers per unit volume. On the other hand, increasing salt concentration decreases the rate of polymer dynamics dramatically decreasing Li^+ transport as well (to a lesser extent) TFSI transport.

Other Polymer Architectures In summary, simulation studies of SPEs based on linear PEO have revealed that strong binding of ether oxygen to Li^+, while facilitating dissolution of lithium salts, reduces the mobility of Li^+ by suppressing structural diffusion. Furthermore, the vehicular mechanism is eliminated in the polymer due to negligible center-of-mass motion of the coordinating polymer chain, necessitating interchain hopping for transport, which is found to be a rare event. While both anion and cation motion are found to be coupled to local polymer relaxation, the anion mobility is found to be significantly greater than that of the strongly bound Li^+ in the PEO-based SPEs, leading to very low transference numbers. Finally PEO crystallizes at around 60°C, precluding its use at lower temperatures due to very poor transport of Li^+ in the crystalline phase. On the other hand, about 60°C (in the molten state), PEO does not provide any mechanical properties that would allow for elimination of a separator, a major potential advantage of SPEs

Comb-Branched Polyethers Comb-branch polyethers with architectures similar to that shown in Fig. 13 have been investigated in efforts to develop SPEs that take advantage of the ability of oligoethers to coordinate Li^+ while at the same time (1) preventing crystallinity due to use of short side chains and (2) allowing in principle for separate optimization of the backbone properties from those of the side chains. The ideal comb-branch SPE might, for example, use a glassy backbone polymer, thereby resulting in good mechanical properties, while Li^+ transport is carried out by flexible ether side chains. The use of relatively short side chains not only reduced/prevents crystallinity, but may also facilitate interchain hopping, which is necessary for large-scale Li^+ transport in SPEs, due to sharing of Li^+ cations between side chains. The optimization of the properties/chemical structure of comb-branch SPEs would be greatly facilitated by an improved understanding of Li^+ transport mechanisms in these polymers, particularly the roles played by the polymer backbone and side chains in ion transport.

MD simulations of comb-branch polyethers of the structure shown in Fig. 14 ($PEPE_5$) have been performed [60]. SPEs formed from this comb-branch polymer have also been studied experimentally [70–72]. A comparison of the ionic conductivity of SPEs with LiTFSI and this comb-branch polymer from simulation and experiment, along with the conductivity of a linear PEO SPE with same salt concentration is shown

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 14 Ionic conductivity in comb-branch SPEs from simulation and experiment

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 15 Conformational relaxation time as a function of position of the dihedral in comb-branch polymer electrolytes from MD simulation

in Fig. 14 [60]. Good agreement between experiment and simulation is apparent. Furthermore, the conductivity of the comb-branch SPE is very similar to that of the linear PEO SPE. The slightly higher conductivity in the linear PEO SPE is facilitated by the lower molecular weight (2,380 Da) of the linear polymer compared to the comb-branch (around 6,000 Da).

Analysis of the MD simulations of the $PEPE_5$ reveal that Li^+ occurs primarily by hopping of the cation from one side chain to another [60]. The six oxygen atoms of the side chains facilitated coordination of Li^+, as anticipated. However, a fraction of Li^+ cations are partially coordinated by the polyether backbone. These cations have very slow dynamics and do not contribute appreciably to Li^+ motion. The slow dynamics of cations partially coordinated by the chain backbone can be understood by considering conformational dynamics in the comb-branch polymer. Figure 15 shows conformational relaxation time, based on decay of the O–C–C–O dihedral autocorrelation function, as a function of position of the dihedral. "0-0" indicates backbone dihedrals, while "5-6" is the last O–C–C–O dihedral on the side chain. Figure 15 reveals that while conformational transitions near the free end of the side chains are similar to those in the linear PEO SPE, those closer to the backbone, and particularly the backbone itself, are significantly slower due to steric crowding. Those Li^+ complexed by the slowest dihedrals show the lowest mobility.

Interestingly, despite slower dihedral dynamics for the polymer backbone on the comb-branch polymer, the overall Li^+ mobility is comparable to that in the linear PEO SPE. Hence, those Li^+ not complexed by the backbone in the comb-branch SPE exhibit higher mobility than in the linear PEO SPE, indicating that the short side chain architecture does promote interchain hopping, as hoped for. Furthermore, it appears that Li^+ mobility, at least for those not complexed by the backbone, is largely independent of backbone motion [60]. This independence is further demonstrated in Fig. 16, which shows the influence of backbone dihedral barriers in the $PEPE_5$ SPE on ion mobility. When the backbone dihedral barriers are increased, the polymer backbone becomes glassy on the timescale of the simulations. Despite the elimination of backbone conformational dynamics, the mobility of the ions is reduced by less than a factor of 2, less than that observed in the linear PEO SPE when the barriers was increased by only 1.3 kcal/mol (see previous discussion). Furthermore, Li^+ diffusion increased by about 30% when a repulsive interaction between the backbone ether oxygen atoms and Li^+ was introduced, thereby eliminating the role of the backbone in cation coordination. In summary, simulations support the supposition that a comb-branch copolymer with ether side groups and a glassy, noncoordinating backbone would show conductivity comparable to or even

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 16 Li^+ and anion diffusion in a $PEPE_5$ showing influence of dihedral barriers on ion mobility

superior to ether-based polymers, with improved mechanical properties.

Finally, it may seem reasonable that shortening the ether side chains (to less than six ether oxygen atoms) would support interchain hoping by promoting multiple side-chain coordination of Li^+. Combined with a noncoordinating backbone, however, shorter side chains could be effective in increasing Li^+ mobility.

Single-Ion Conductors As discussed above, one of the disadvantages of PEO-based SPEs is their low transference number due to relatively high anion mobility. Large-scale anion motion in comb-branch SPEs can be eliminated by attaching the anions to the polymer, such as shown in Fig. 17. Here, the TFSI anion of LiTFSI has been attached to the oligoether side chain to form a polyanion with essentially no large-scale mobility, resulting in a single-ion conductor. Here, the ether oxygen to Li^+ ratio is controlled by the length of the side chains. Unfortunately, simulations show that reducing the mobility of the TFSI anion has a deleterious effect on Li^+ mobility, particularly for low temperatures and short side chains/small EO:Li^+ ratios. Simulations reveal that anions play an important role in the ability of Li^+ cations to undergo interchain jumps in PEO-based electrolytes, particularly at higher ion concentrations. Attaching TFSI to the side chain reduces the mobility of the anion and apparently its ability to assist in Li^+ hops. The effect is reduced for longer side chains, due both to decreased importance of anions for the lower salt

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 17 Structure of a PEO-based single ion conductor

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 18 A comparison of the lithium diffusion coefficient in PEO-based single ion conductors (Fig. 14) and PEO-based binary comb-branch polymer electrolytes (Fig. 10) from simulations

concentration, and possibility increased anion mobility on the longer tether.

Figure 18 shows the lithium diffusion coefficient in a PEPE binary (free anion) SPE (Fig. 13) and single ion conductors (Fig. 17) from unpublished simulations for various EO:Li ratios. Simulation reveals that the lithium diffusion coefficient in the single ion conductor is about a factor of 2–6 lower than in the binary PEO SPEs. Note that unlike the binary PEO SPEs, the PEPE-based single ion conductor does not show a maximum in conductivity around EO:Li = 20, but increases monotonically with increasing EO:Li, again due to the deleterious effect on Li^+ mobility of attaching the anion as discussed above.

Finally, while attaching the anion to the polymer has the advantage of improving transference number

(all charge is carried by Li^+), reducing the already low mobility of Li^+ is a major disadvantage. Addition of a solvent/plasticizer to form a gel, single-ion conductor electrolyte is a possible solution. Simulations reveal that gel electrolytes formed from 37 wt.% ethylene carbonate plasticizer with a $PEPE_5$:TFSI single ion conductor show dramatic improvement in ionic conductivity over the nonplasticized single ion conductor, particularly at lower temperatures. Here, conductivity, which is due to Li^+, is comparable to that for the comb-branch binary SPE, where the majority of charge is carried by the free anion. Simulations reveal that the primary role of the EC solvent is to "plasticize" the polymer, i.e., increase the rate of polymer conformational transitions, and not to coordinate and transport Li^+; EC does not compete well with oligoethers for coordination of Li^+. These results from unpublished work are consistent with the recent findings for PEO/LiTFSI plasticized with carbonate solvents [37].

Modeling of Ionic Liquid Electrolytes

Room-Temperature Ionic Liquid-Based Binary Electrolytes

Two types of ionic liquid electrolytes have been extensively studied: (1) ionic liquid solvents comprised of ions shown in Fig. 19 doped with lithium salts and called binary room temperature ionic liquid (RTIL) electrolytes; and (2) molten salts, in which the lithium solvating host such as oligoether is attached to an anion such as $TFSI^-$, thus forming an ionic liquid (also called molten salt) without a free solvent. Binary ionic liquid electrolytes have attracted a significant attention because of their negligible vapor pressure; good thermal and electrochemical stability in the range of 5.3 V [73]; good dissolution properties with many organic and inorganic compounds and lithium salts; and low flammability [74]. A wide variety of possible anions and cations offer a potential to tailor RTIL properties to a particular application. The solvent free molten salt electrolytes (type b) are attractive due to their potential to eliminate ion concentration polarization during battery operation. However, low oxidative stability of oligoether solvating host attached to anion and low conductivity counterbalance this advantage.

Hundreds of MD simulation studies of pure RTIL solvents have been reported [75, 79, 80]. Accurate prediction of density, heat of vaporization, conductivity, viscosity, self-diffusion coefficients, structure factors, and crystal structure was reported [75, 80–83] for RTIL comprised of ions listed in Fig. 19, while other MD studies [84] reported ion transport an order of magnitude slower than experiments. An order of magnitude slower prediction of RTIL transport cannot be fully attributed to the absence of polarization in the force field as turning off polarization slowed down ion transport only by a factor of 1.3–3 and not an order of magnitude in published simulations [75, 85]. The relation between ion transport, ion volume, and a combination of the heat of vaporization and the cation–anion binding energy has been reported [76].

Unlike the tremendous interest in simulating pure RTIL solvents, only a very limited number of MD simulations studies of ILs doped with lithium salts have been reported: $[pyr_{11}]$[TFSI] doped with LiTFSI and $[pyr_{13}]$[TFSI] doped with LiTFSI (at 303, 333, 393, and 500 K) [86], [1-ethyl-2,3-dimethyl-imidazolium (emmim)]$[PF_6]$ doped with $LiPF_6$ (at 523 K) [87], and [1-butyl-2,3-dimethyl-imidazolium (bmmim)][TFSI] doped with LiTFSI (at 400 K) [88]. See Fig. 19 for ion notation. MD simulations [86] employing a polarizable force field accurately captured ion self-diffusion coefficients of $[pyr_{13}]$[TFSI] doped with 0.25 mol LiTFSI as shown in Fig. 20, indicating good predictive capabilities of MD simulations for ion transport properties. The lithium self-diffusion was the slowest, while pyr_{13}^+ cation diffusion was the fastest in this IL. In a contrast to this work, MD simulations [88] of [bmmim][TFSI] doped with LiTFSI using the nonpolarizable force field predicted ion transport less than an order of magnitude slower than pfg-NMR data. Such poor ion transport predictive capabilities reported for [bmmim][TFSI] doped with LiTFSI [88] is likely due to inadequate force field development efforts as the nonpolarizable force fields could be designed to have much more accurate prediction of ion transport (within a factor of 2–3) [80, 85].

In $[pyr_{13}]$[TFSI] doped with 0.25 mol LiTFSI the Li^+ cation was found to be coordinated on average by slightly less than four oxygen atoms. The Li^+ coordination by four $TFSI^-$ and by TFSI clusters was observed, in contrast to conclusion of infrared and Raman studies of alkyl-substituted imidazolium-TFSI-based IL doped with LiTFSI [89]. The spectroscopic study found for

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 19 A list of representative anion and cations in ionic liquid solvents used in MD simulations [75–78]

low to moderate LiTFSI mole fractions, $0.08 < \times < 0.2$, the $[Li(TFSI)_2]^-$ solvating cage involving bidentate coordinations of Li^+ with two oxygen atoms of one anion in the trans (C_2) conformation and two oxygen atoms of the other anion in the cis (C_1) conformation. It is not clear how to explain the difference between MD results and analysis of the spectroscopic study. Turning off ion polarization in MD simulations dramatically reduced probability of forming extended $(Li^+)_n(TFSI^-)_m$ aggregates but did not result in the Li^+ cation solvation by only two $TFSI^-$.

The mechanism of lithium transport was also studied in $[pyr_{13}][TFSI] + 0.25$ LiTFSI [86]. The Li^+ cation transport was found to occur primarily by exchanging $TFSI^-$ anions in the first coordination shell of a Li^+ with a smaller (~30%) contribution also due to Li^+ cations

diffusing together with their first coordination shell. It is important to note that despite high conductivity of IL-based electrolytes ($\sim 10^{-2}$ S/cm) the lithium contribution to the charge transport remains quite low. In fact, conductivity due to the Li^+ cation transport only in $[pyr_{13}][TFSI]$ + 0.25 LiTFSI was found to be somewhat greater than that for a model poly(ethylene oxide)(PEO-based)/LiTFSI polymer electrolyte but 1–2 orders of magnitude lower than conductivity of ethylene carbonate/LiTFSI liquid electrolyte depending on temperature [86].

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 20 Ion self-diffusion coefficients of $0.25Li^+TFSI^-$-$0.75mppy^+TFSI^-$ from MD simulations and pgf-NMR experiments (Used from Ref. [86] with permission of ACS)

Solvent-Free Molten Salts Electrolytes

MD simulations provided insight into the lithium coordination and transport mechanism in the solvent-free molten salt electrolyte comprised of $TFSI^-$ tethered to oligoethylene oxide (EO) ($EO_{12}TFSI^-/Li^+$) [39]. Behavior of $EO_{12}TFSI^-/Li^+$ was contrasted with the ion transport and aggregation in a binary solution of EO_{12} doped with LiTFSI salt (EO_{12}/LiTFSI). It was found from MD simulations and experiments that attaching $TFSI^-$ anion to the chain end of the oligoether resulted in reduction of conductivity by one order of magnitude at 423 K and two orders of magnitude at room temperature, as shown in Fig. 21. The lithium cations were separated from $TFSI^-$ anion by oligoether in most instances (75–90%) for both EO_{12}/LiTFSI and $EO_{12}TFSI^-/Li^+$. For the EO_{12}/LiTFSI binary electrolyte, the fraction of separated $Li^+/TFSI^-$ ions was similar to the degree of ion uncorrelated motion (α_d, see Eqs. 3–4) indicating mostly uncorrelated Li^+ and $TFSI^-$ ion motion in agreement with conclusions the coordinated pfg-NMR and conductivity study [69]. In contrast to this, a significant correlation between lithium and anion motion was found in $EO_{12}TFSI^-/Li^+$ molten salt with a degree of ion uncorrelated motion (α_d) being about ($\sim$45–55%).

The Li^+ cation self-diffusion coefficient in a binary EO_{12}/LiTFSI electrolyte was dominated (90%) by Li^+ vehicular diffusion of the Li^+ with an EO_{12} solvent. In $EO_{12}TFSI^-/Li^+$ molten salt electrolyte, half of the

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 21 Conductivity of binary electrolytes EO_{12}/LiTFSI and EO_nTFSI^-/Li^+ IL from MD simulations (n = 12) and experiments (n = 13). Hayamizy data for binary electrolyte from Ref. [69] are also shown (Reproduced with permission of ACS from Ref. [39])

Li^+ motion was attributed to the Li^+ motion with $EO_{12}TSFI^-$ anion, with the other half being due to the solvating group exchange that involves a Li^+ local motion along the chain, Li^+ motion together with its coordination shell and interchain hopping. Only solvating group (EO and TFSI) exchange contributes to charge transport in $EO_{12}TFSI^-/Li^+$, as vehicular motion results in transport of neutral species accounting for reduction of conductivity by a factor of 2. Interestingly, the Li^+ solvating group exchange rate was found in the binary electrolyte (EO_{12}/LiTSFI) being quite similar to that in $EO_{12}TFSI^-/Li^+$ at high-temperature range (393–423 K). However, as temperature decreased, the Li^+ exchange of oligoether solvating part of anions in molten salts became slower than that the Li-oligoether exchange found in the binary electrolyte.

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 22 Conductivity of lithium dilithium ethylene dicarbonate (Li_2EDC) > lithium methyl carbonate (LiMC) from MD simulations [91] compared to conductivity of EC/LiTFSI from MD simulations [36]

SEI Model Compounds

The ability of an electrolyte to form a stable and conductive SEI on electrodes is paramount for efficient battery operation as discussed previously. Solubility of SEI model compounds by DMC and EC reduction on anode was studied in simulations by Tasaki et al. [90]. They suggested the following order for the SEI forming salts to be soluble in DMC and EC: lithium dilithium ethylene dicarbonate (Li_2EDC) > lithium methyl carbonate (LiMC, $LiOCO_2CH_3$) > LiOH > $LiOCO_2C_2H_5$ > $LiOCH_3$ > LiF > $(LiCO_2)_2$ > Li_2CO_3 > Li_2O. This order agreed with experiments performed in DMC quite well [90]. MD simulations [91] have been used to investigate the structure and transport of two SEI components: Li_2EDC and LiMC. These SEI components are commonly reported in the outer part of SEI [92, 93] and probably exist in a disordered state in it because of the high fraction of other components present, thus inhibiting formation of the crystalline phase.

Ionic conductivity of Li_2EDC and LiMC predicted from MD simulations is shown in Fig. 22. At high temperature, conductivity of alkyl carbonates is comparable to that of liquid electrolytes such as EC/LiTFSI [36]. However, the much stronger temperature dependence of alkyl carbonate conductivity compared to typical liquid electrolytes (e.g., EC/LiTFSI) leads to significantly lower conductivity of alkyl carbonates at lower temperature compared to liquid electrolytes. The extrapolated conductivity of Li_2EDC at −30°C is on the order of 10^{-10} S/cm, suggesting that an SEI comprised primarily of Li_2EDC with typical width of ~10 nm would give rise to significant SEI layer resistance. Conductivity of LiMC is somewhat greater than that for Li_2EDC but also would result in a quite low conductivity of SEI. The extrapolated Li_2EDC conductivity from MD simulations is around 2×10^{-8} S/cm at room temperature in a good agreement with the value 10^{-9} S/cm measured by Phillip Ross group from LBNL [94]. These results are in stark contrast with a dramatically faster ion transport in Li_2EDC predicted by Tasaki et al. [90] at room temperature. The lithium diffusion in Li_2EDC of 8×10^{-12} m^2/s predicted from Tasaki et al. [90] is approximately four and a half orders of magnitude higher than the extrapolated from high temperature D (Li^+) of 2×10^{-17} m^2/s self-diffusion from Borodin et al. [91].

Molecular Dynamics Simulations of Electrode/Electrolyte Interfaces

Graphite Interface

Experimental studies [95–98] of the secondary cells at low temperature (less than −20°C) have consistently found that $R_{ct} > R_{SEI} > R_{bulk}$ for mixed carbonate solvents using conventional $LiBF_4$, $LiPF_6$, and LiBOB salts for a number of tested cells. Thus, the charge transfer resistance (R_{ct}) resistance is the dominant contribution to the secondary lithium cell resistance at low temperature, followed by R_{SEI} (SEI resistance) and R_{bulk} (bulk electrolyte resistance). Similar results have been reported for ionic liquid [99] and polymeric electrolytes [100]. Therefore, the conventional matrix for choosing liquid electrolytes based upon bulk electrolyte conductivity and its ability to form a stable SEI layer needs to be augmented with understanding and optimization of the electrolyte interfacial properties such as interfacial resistance. Intriguingly, the interfacial resistance does not always correlate with the bulk electrolyte resistance creating both opportunities and additional challenges for optimization of electrolyte materials. Importantly, the charge transfer resistance is commonly linked to the Li^+ cation desolvation process from electrolyte and its intercalation into SEI layer or an electrode followed by the actual electron transfer reaction. The length scale for the desolvation process is on the scale of nanometers and, therefore, could be accessed via molecular simulations together with the fundamental electrolyte properties such as conductivity, ion self-diffusion, and the degree of ion aggregation.

MD simulations were performed on EC/$LiPF_6$ and EC:DMC(3:7)/$LiPF_6$ 1 M electrolytes next to the material blocking for anion and solvent but nonblocking to lithium cation and measure the interfacial resistance and free energy due to lithium desolvation from electrolyte. At the initial stage, graphite was chosen as the electrode material and did not include an SEI or controlled voltage between electrodes. MD simulations have been performed at 298 K for two sets of EC/$LiPF_6$ and EC:DMC(3:7)/$LiPF_6$ at 1 M salt concentration next to graphite as shown in Fig. 23 for EC:DMC (3:7)/$LiPF_6$ | Graphite. The electron transfer process has not being included in the simulated model.

The free-energy profile for the lithium desolvation ($\Delta G(z)$) in the range of k_BT could be obtained from equilibrium MD simulations using Eq. 5:

$$\Delta G(z) = -k_b T \cdot \log(\rho(z)) \tag{5}$$

where k_B is the Boltzmann constant, T is temperature, and $\rho(z)$ is the normalized lithium probability profile calculated perpendicular to graphite (z-direction). Figure 24 shows the lithium free-energy profile $\Delta G(z)$ calculated from Eq. 2 using the lithium cation probability profile obtained from 20 ns MD simulations with the first 10 ns omitted as equilibration. The free-energy

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 23 A snapshot of the simulation box used for calculating the free-energy barrier of the lithium desolvation energy

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 24 The free-energy profile for the lithium cation desolvation from EC:DMC(3:7)/$LiPF_6$ at 1 M electrolyte at 298 K calculated using the Li^+ probability profile from equilibrium MD simulations and the integration of the constrained force method. $Z = 0$ at the position of hydrogen atoms of graphite

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 25 The lithium cation desolvation free-energy profile for EC/$LiPF_6$ and EC:DMC(3:7)/$LiPF_6$ 1 M electrolytes next to graphite at 298 K

profile $\Delta G(z)$ shows a local minimum of −0.5 kcal/mol at ~5 Å from the graphite indicative of a preferential lithium position in the Helmholtz plane. The free energy sharply increases as the lithium approaches graphite and is forced to desolvate from electrolytes at distances closer than 4 Å from graphite. Note, that even long (10 ns) simulation trajectory allowed us to sample the free-energy profile only for energies lower than 1.5 kcal/mol, indicating that an advanced sampling technique needs to be used.

The $\Delta G(z)$ was also calculated using the integration of the constrain force technique, in which a Li^+ is constrained at a certain position relative to the surface and the constraining force is calculated (for all points shown in Fig. 24). This methodology was previously used to investigate small molecule permeation through a lipid bilayer [101]. The simulations were 6–12 ns for each constrained distance. The integral of the constrained force gives a free-energy profile that is also shown in Fig. 24. An excellent agreement between two methods of calculating the free-energy profile is observed for free energies below 1 kcal/mol, where the equilibrium MD is expected to provide an adequate sampling.

Two independent sets of simulations of EC/$LiPF_6$ 1 M | graphite for calculating $\Delta G(z)$ have been performed in order to ensure convergence of simulation results and their independence from the state of the lithium coordination shell. In the first simulation, the test-lithium was initially solvated only by EC molecules in the first coordination shell, while in the second set of simulations the lithium (with the constrained distance to graphite) had one PF_6^- anion in its first coordination shell. The free-energy profiles for the lithium desolvation from these electrolytes were calculated by the integration of the constrain force and are shown in Fig. 25.

A similar barrier of $\Delta G(z)$ is observed for EC/$LiPF_6$ and EC:DMC(3:7)/$LiPF_6$ 1 M electrolytes next to graphite is in accord with the experimental evidence. If one assumes that the charge-transfer reaction occurs when a Li^+ is located between outer layer carbon and hydrogen atoms then a value of $\Delta G(z)$ around 12–19 kcal/mol is obtained, which is consistent with the experimental [102] activation energies of 16.4–17 kcal/mol.

$LiFePO_4$/Electrolyte Interface

Lithium iron phosphate ($LiFePO_4$) is an attractive cathode material for lithium-ion batteries for a number of reasons, including good thermal stability, low fabrication costs (from abundant starting materials), nontoxicity, a reasonably high theoretical specific capacity and an inherently flat voltage – time discharge profile [103]. Interfacial impedance for $LiFePO_4$ cells, which includes both anode/electrolyte and cathode/electrolyte contributions, can be an important source of overall cell impedance at rates and temperatures of practical interest, with both conventional solvent–based electrolytes and ionic liquid–based electrolytes [99]. It has long been held that resistance to Li^+ transport through the anode/electrolyte interface contributes significantly to cell impedance due to the presence of a poorly conducting SEI that forms on most anode materials due to reduction of the electrolyte [104]. Recently, more attention has been focused on contributions of Li^+ transport across the cathode/electrolyte interface to cell impedance. Interfacial effects, particularly those associated with Li^+ desolvation during intercalation, are thought to play an important role in determining the impedance of $LiFePO_4$-based cathodes [105, 106].

An atomistic simulation MD simulation of a common carbonate-based organic electrolyte, ethylene carbonate:dimethyl carbonate (EC:DMC = 3:7) with approximately 1 mol/kg $LiPF_6$, referred to as the organic liquid electrolyte or OLE, and an ionic liquid–based electrolyte (ILE), 1-ethyl 3-methyl-imidazolium: bis(fluorosulfonyl)imide ($EMIM^+$:FSI^-) with 1 mol/kg LiFSI, in contact with $LiFePO_4$ has been carried out [107]. Simulations were carried out using quantum chemistry–based polarizable force at 363 K on a 3-D periodic orthorhombic $LiFePO_4$ film + electrolyte systems such as shown in Fig. 26. POMF studies analogous to those for graphite were carried out in order to investigate the free-energy profile of bringing a Li^+ cation from the bulk electrolyte to the $LiFePO_4$ surface.

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 26 Snapshot from an MD simulation of an ionic liquid electrolyte in contact with $LiFePO_4$

Poisson Potential Profile and Double Layer Structure for the ILE The Poisson potential for the ILE is shown in Fig. 27. In addition to the potential for the $LiFePO_4$/ILE system, the potential for the $LiFePO_4$ film alone (in vacuo) is shown. For the $LiFePO_4$ in vacuo, the potential at the outer edge of the $LiFePO_4$ surface, i.e., $y \approx 0.5$ Å ($y = 0$ at the surface lithium layer, with y being the direction of the surface normal) reaches a constant value which is arbitrarily assigned a value of 0 V. For $LiFePO_4$ in contact with the ILE system, the potential exhibits structure with a period of 2.5–3 Å, oscillating between negative and positive values, which

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 27 Poisson potential and Li^+ free energy as a function of position with respect to the interface with $LiFePO_4$ in an ionic liquid electrolyte

reflects the atomic-scale surface-induced ordering in the electrolyte. The surface-induced local structure in the ILE reflected in the potential is clear in the snapshot of the system (Fig. 26) FSI^- and $EMIM^+$ are strongly segregated in the surface layer, with the former concentrated near surface Li^+ and the latter near surface oxygen atoms. The electrostatic potential reaches the bulk value (arbitrarily set to 0 V) at about 1 nm from the surface, indicating a relatively narrow double layer. The potential at the outer edge of the $LiFePO_4$ surface (the electric surface potential) is about −0.25 V with respect to the bulk electrolyte. Hence, the presence of the ILE results in a negative potential at the $LiFePO_4$ surface. This negative potential is due to the excess negative charge in the electrolyte between 1.5 and 2.5 Å, resulting from excess FSI^- in the interfacial layer. Between the potential minimum near the surface and the next minimum at around 4 Å, there is a large positive potential of about 0.6 V with respect to the bulk electrolyte.

Poisson Potential Profile and Double Layer Structure for the OLE The Poisson electrostatic potential for the $LiFePO_4$/OLE is shown in Fig. 28. Also shown is the potential for the $LiFePO_4$ film alone (in vacuo). The potential at the outer edge of the $LiFePO_4$ surface is negative with respect to the bulk (around −0.8 V). This electric surface potential is much more negative than observed for the ILE because of the propensity of negatively charged carbonyl oxygen atoms from the carbonate molecules to approach the surface and coordinate Li^+ and the lack of a strong positive charge (such as the hydrogen and nitrogen atoms in $EMIM^+$) to offset the resulting negative charge density. Between the negative potential minimum near the surface (around 1 Å) and the next minimum at around 5 Å, there is a positive potential comparable in magnitude to that observed in the ILE. The electrostatic potential reaches a constant (bulk) value at about 1 nm from the surface as was observed for the ILE electrolyte, indicating a narrow double layer.

The carbonyl oxygen atoms of the carbonate molecules, which have an appreciable negative charge (−0.4e to −0.5e) and are principally responsible for solvating Li^+ in bulk EC/DMC electrolytes [35], play the same role for the surface Li^+. Unlike the ILE, however, there are no exposed highly positively charged atoms in the OLE available to solvate the $LiFePO_4$ surface oxygen atoms. The CH_2/CH_3 groups in EC/DMC have a small positive charge in the range of +0.1e to +0.15e and the hydrogen atoms from these groups are the main coordinating atoms for the surface O atoms. This results in a dense layer of EC and DMC centered 3–4 Å from the surface as indicated by atomic and molecular density profiles.

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 28 Poisson potential and Li^+ free energy as a function of position with respect to the interface with $LiFePO_4$ in an organic liquid electrolyte

Free Energy of Li^+ as a Function of Position Relative to the $LiFePO_4$ Surface The potential of mean force (POMF), i.e., the free energy as a function of the position of a Li^+ relative to the $LiFePO_4$ surface, is shown in Fig. 27 for the ILE/$LiFePO_4$ system and in Fig. 28 for the OLE/$LiFePO_4$ system. For both the OLE and ILE systems the POMF is qualitatively similar to the Poisson potential. First, there is little structure in the POMF beyond 1 nm from the surface. Similarly, both the POMF and Poisson potential exhibit a maximum (in energy and potential, respectively) around 3 Å from the surface and a minimum very near the surface. However, a Li^+ cation interacting with the Poisson potential would experience a much larger positive energy at the barrier (note that the potential is in volts and the POMF in kcal/mol) and a much lower energy near the surface than is indicated by the POMF. In is important to note that the POMF measures the free energy (thermodynamic potential) associated with the actual process of bringing of a Li^+ cation to the $LiFePO_4$ surface while the Poisson potential is a plane-average measure of the equilibrium electrostatic potential. The Li^+ will find the lowest free-energy path to the surface and bring negative charge with it, and its presence results in a local restructuring of the electrolyte and electrolyte/$LiFePO_4$ interface.

Interfacial Impedance The total interfacial impedance from the bulk electrolyte to a point y relative the $LiFePO_4$ surface can be estimated (in units of Ω-cm^2) as the integral of the local resistivity:

$$R_{\text{int}}(y) = \int_{y=14}^{y} -2.71 \times 10^{-9} \frac{kT \exp\left[\frac{\Delta G(y)}{kT}\right]}{D_{Li^+}(y) N_{\text{bulk}} e^2} dy \tag{6}$$

where ΔG is Li^+ free energy, D is the Li^+ diffusion in the y direction, N_{bulk} is the concentration of Li^+ in the bulk electrolyte, and T is temperature. Using values of these quantities as determined from simulation, $R_{int}(y)$ for the ILE and the OLE systems was estimated using Eq. 2 [107]. Results are shown in Fig. 29, where it can be seen that the interfacial impedance for transporting Li^+ from y = 14 Å to about y = 3 Å is very small. In this region, the greater interfacial impedance for the ILE is due to the bulk lower Li^+ diffusion compared to that in the OLE. Beginning at around y = 3 Å, the decrease in Li^+ concentration due to the free-energy barrier observed for both the OLE and the ILE systems results in an increase in resistivity. The free energy of almost 4 kcal/mol, relative to the bulk and the corresponding decrease in Li^+ concentration in this region, does not lead to an appreciable contribution to R_{int}. An important conclusion from this work is that the higher bulk viscosity/lower bulk Li^+ mobility for the ILE compared to the OLE does not appear lead to a significant barrier for transporting Li^+ to the $LiFePO_4$ surface.

Lithium Battery Electrolyte Stability and Performance from Molecular Modeling and Simulations. Figure 29 Predicted interfacial impedance as a function of position

If/when the resistance for Li^+ transport through the electrolyte/$LiFePO_4$ interface is to make a significant contribution to overall cell impedance (in the absence of an SEI layer at the cathode/electrolyte interface), simulations indicate that it is likely due to the final desolvation process associated with intercalation of Li^+ into $LiFePO_4$. The rapid increase in free energy associated with this process leads to large resistivity according to Eq. 2 and a rapid increase in R_{int}, as shown in Fig. 29. Unfortunately, the range of positions (for $y < 0$) over which the free-energy profile used to estimate $N_{Li^+}(y)$ is accurate is unknown. Furthermore, use of Eq. 2 to estimate the equilibrium $N_{Li^+}(y)$ is questionable for $y < 0$ due to adsorption of Li^+ on the surface and the localization of Li^+ into specific channels (galleries). Nevertheless, assuming that the free-energy profile from simulation is valid to $y = -1$ Å, Fig. 29 indicates that interfacial impedance associated with the initial stages of intercalation from the surface into the $LiFePO_4$ gallery is significantly greater for the ILE than the OLE, but in either case is estimated to be quite small. The greater interfacial impedance for the ILE is not due to differences in the energetics of the desolvation process but rather to the much lower propensity of Li^+ to populate the $LiFePO_4$ surface in the ILE.

While interfacial impedance associated with bringing the cation to the $LiFePO_4$ surface and the initial stages of intercalation appears to be small at 363 K, the situation may be quite different at lower temperatures. Equation 2 can be applied at any temperature of interest assuming that $D_{Li}+(y)$ and $\Delta G_{Li}+(y)$ are independent of temperature. The estimated interfacial impedance at 253 K so calculated is shown in Fig. 29. Certainly $D_{Li}+(y)$ will decrease with temperature, particularly for the ILE, which, combined with increased interfacial structure with decreasing temperature, makes the estimated interfacial impedance at 253 K shown in Fig. 29 lower than would be obtained from direct determination of $D_{Li}+(y)$ and $\Delta G_{Li}+(y)$ at lower temperatures. The estimated contributions of the desolvation process associated with the initial stages of Li^+ intercalation are much greater at the lower temperature than at 363 K, particularly for the ILE. This result is intriguing in light of recent experimental studies that claim that interfacial impedance at the cathode electrode is important at sub-ambient temperatures for OLE-based systems, albeit, desolvation process on the anode was found to have a higher activation energy [108, 109]. Simulation results indicate that this could be exacerbated by the use of ILEs.

Summary

In summary, MD simulations of an OLE and an ILE in contact with $LiFePO_4$ reveal surface-induced structure in the electrolytes that extends about 1 nm from the $LiFePO_4$ surface. The Poisson electrostatic potential was found to be large and negative within about 1 Å of the surface and large and positive in the region of 2–4 Å from the $LiFePO_4$ surface. The negative potential at the $LiFePO_4$ surface results from an excess of negative charge from the electrolyte near the surface that participates in the coordination of the surface Li^+ atoms. The positive potential slightly further from the surface results from the orientation of the electrolyte molecules at the $LiFePO_4$ surface. This positive electrostatic potential is qualitatively consistent with a free-energy barrier for bringing Li^+ cations from the bulk electrolyte to the surface found to be 4 kcal/mol. However, this barrier and the corresponding decrease in Li^+ concentration due to lack of coordinating atoms (carbonyl oxygen atom) in the OLE in this range of distances from the interface, large local positive charge in the ILE, and the highly structured nature of the interfacial electrolyte, which reduces its ability to solvate Li^+, do not contribute significantly to interfacial impedance.

The latter, if and when important, appears to be dominated by the desolvation process associated with intercalation of Li^+ into the galleries of $LiFePO_4$.

Future Directions

The future will see increased reliance on modeling for understanding of electrolyte electrochemical stability, electrolyte/electrode interactions, and the structure and properties of the SEI layer. Particularly valuable will be simulation methods that accurately reproduce reactions between the electrolyte, salts, and electrolyte additives with the electrodes. These methods, which will include QM and reactive molecular dynamics methods, will be invaluable in providing fundamental insight into the mechanisms of electrolyte decomposition, reactions leading to the formation of the SEI as well as in predicting the structure of the SEI. As efforts toward developing high-voltage cathodes increase, simulations will play an important role in the development of electrolytes that are oxidatively stable at the higher voltages as well as in development of strategies for passivating the cathode surface.

Acknowledgments

The authors are grateful to the Department of Energy under Contract grant DE-SC0001912 to University of Utah and Air Force Office of Scientific Research contract number FA9550-09-C-0110 for the financial support of this work. Diffraction A phenomenon which occurs when a propagating wave encounters or interacts with an object. Diffraction techniques have become a standard method for the investigation of the atomic structure of matter.

Nuclear magnetic resonance (NMR) A condition in which magnetic nuclei in the presence of an external magnetic field absorb and reemit electromagnetic radiation (in the radiofrequency regime). The energy absorbed depends on the strength of the magnetic field and a number of chemical and structural properties of the matter under investigation.

Photoelectron The electrons ejected from matter after having absorbed electromagnetic radiation of a particular wavelength.

Relaxation The process by which a system returns to equilibrium after a perturbation, usually characterized by a specific time *t*.

Solid electrolyte interphase (SEI) Electrolyte decomposition products, both organic and inorganic, that form a protective layer on the electrodes (predominantly the anode) of lithium-ion batteries which is necessary for optimal performance and cell longevity.

Definition of the Subject and Its Importance

Despite their spectacular success in portable electronics applications, continued technical advances of lithium-ion batteries are crucial to establishing large-scale storage applications such as electric vehicles and enabling development of renewable intermittent energy sources, i.e., wind and solar. Paramount considerations in realizing scaled-up battery systems are safety, cost, energy density, and service lifetime. Some of these applications also require rapid charge and discharge capability. To move beyond the current generation of lithium-ion batteries, it is necessary to understand some of the outstanding materials issues of the individual components (i.e., electrodes and electrolytes) as well as the battery system as a whole where the components interact under conditions of elevated temperature and electric current flow.

The rational design of compounds, complexes, and systems consisting of them for particular applications is the basis of modern materials science. The advent of powerful computing hardware and software in the last decade has made great strides in predicting material properties without doing a single experiment. On the other hand, the need for experimental verification has often resulted in the discovery of new scientific principles and behavior, and driven the development of not only the materials themselves but also ever more potent and versatile experimental tools. The purpose of this article is to describe several analytical methods with examples of their use in investigating material properties of rechargeable lithium battery cell components and systems, especially in the context of the outstanding technical challenges to further development. In addition, a few examples detailing how computational studies can aid in the interpretation of experimental results and in the development of new materials will be presented.

Introduction

Since their successful commercialization in the 1990s, extensive research has been carried out on lithium-ion batteries. The main material challenges have been recently summarized by Goodenough and Kim [1]. A lithium-ion battery cell consists of three main components: two electrodes – an anode (the negative terminal), and a cathode (positive terminal), as well as a non-aqueous electrolyte which physically separates the two electrodes, but allows conduction of ions between them during cycling (discharging and charging) of the battery. The work of Whittingham on titanium(II) sulfide as a cathode material was a breakthrough in the field and generated a lot of interest in utilizing intercalation chemistry for energy storage applications [2]. Since then, lithium metal oxides –$LiCoO_2$, $LiNiO_2$, $LiMn_2O_4$– have been employed as cathode materials. Due to the high reactivity of lithium metal, safety concerns have prompted the use of lithiated graphitic carbon as a replacement anode. Typical liquid electrolytes include lithium salts dissolved in organic carbonates.

The advancement of battery technology ultimately resides in a fundamental understanding of the structural, chemical, and electronic changes in the component materials that occur upon cycling. Experimental techniques commonly used in battery science can be broadly categorized as probing either the long-range or local structure. For a significant advancement in the field, both sets of techniques need to be utilized effectively to fully understand the chemistry and structure-property relationships of materials.

Electrochemistry

The overwhelming majority of commercially available anode and cathode materials for Li-ion batteries undergo an insertion reaction. The reaction mechanism involves the migration of Li^+ cations into (insertion, intercalation) and out of (extraction, deintercalation) cathode and anode materials, both of which often have a layered or tunnel structural motif. Since Li metal anodes have been largely replaced by graphitic carbon due to safety concerns, the positive electrodes in Li-ion batteries act as a source of lithium. During discharge, Li^+ migrates from the anode, through the electrolyte, to the cathode. Concomitantly, an electron is released for every Li^+ ion involved in the migration to an external circuit where it can power a device and perform work. The half-reactions, or one component of a redox (reduction-oxidation) reaction, of the two electrodes composed of lithium metal oxides of the form $LiMO_2$ (where M is a transition metal) and graphite can be written as,

$$LiMO_2 \leftrightarrow Li_{1-x}MO_2 + xLi^+ + xe^-, \quad (1)$$

for the cathode and

$$xLi^+ + xe^- + 6C \leftrightarrow Li_xC_6, \quad (2)$$

for the anode, respectively. In the $LiMO_2$ case, the transition metal gets oxidized from M^{3+} to M^{4+} during charging, with a subsequent reduction from M^{4+} to M^{3+} during discharge. Initially, layered $LiNiO_2$ was considered a promising cathode material considering it is cheaper and less toxic than cobalt [3], but the delithiated compounds were recognized as being too reactive with the organic electrolyte, posing a significant safety hazard. Moreover, Li–Ni exchange in the material over repeated cycles drastically hindered performance [4]. Issues stemming from environmental concerns and the cost of cobalt have motivated the study of similar layered compounds containing little to no Co as replacement cathode materials, such as $LiNi_{1-y}Co_yO_2$ [5], $LiMnO_2$ [6], $LiNi_{1-y}Mn_yO_2$ [7], and $LiNi_{1-y-z}Mn_yCo_zO_2$ [8, 9]. Structural instability of the electrodes, in conjunction with unavoidable side reactions which occur in the cell, limits the amount of charge and discharge cycles a battery can undergo. The rate of cycling also has a pronounced effect on the structure of many electrode materials and is an important factor in the depletion of performance.

A few classes of materials, such as binary copper compounds (copper sulfide CuS and copper oxide CuO) and metal fluorides ($M^{n+}F_n$), undergo a conversion reaction during cycling. These compounds have generated interest as potential electrode materials due to their high specific capacities (~600–1,000 mAh/g) and excellent cycling reversibility [10]. In this reaction mechanism, lithium compounds (lithium sulfide Li_2S, lithium oxide Li_2O, lithium fluoride LiF) are formed along with metal nano-particles during discharging. The overall reaction can be written as

$$M_xX_y + nyL_i \leftrightarrow yLi_nX + xM^0, \quad (3)$$

where X is either O or F, and M^0 denotes a transition metal in the metallic state. The reaction typically involves micron-sized M_xX_y particles which react to form composite materials composed of nano-sized metallic particles (on the order of 1–10 nm) and Li_nX which occurs on the first cycle. In subsequent redox cycles, the size of these particles remains virtually unchanged. The confinement of these metal particles in the lithium salt matrix is thought to play a crucial role in the electrochemical activity in the material. Of the M_xX_y compounds, only metal fluorides are considered as alternative positive electrodes in lithium-ion batteries. This is due to their ionic character, which in turn necessitates higher operating voltages [11, 12]. Unfortunately, fluorides tend to be large bandgap insulators, prohibiting their use in batteries. To circumvent the inherent issues of the fluorides, Amatucci and coworkers have prepared a mixed conductive matrix (MCM) composed of nanocarbon-metal-fluoride composite materials [13, 14]. In a few instances, a conductive oxide such as MoO_3 can also be used to enhance conductivity [15]. The drastic reduction of the metal fluoride particles, along with the presence of the highly conductive matrix in the nanocomposites results in enhanced electrochemical activity and cycling properties. The smaller particle size decreases the tunneling lengths of the electrons during the redox reaction in addition to increasing the available surface area, facilitating the diffusion of Li. The presence of a conducting matrix between the nanograins of the materials allows the reaction to progress.

The choice of electrolytes highly depends on the operating voltages and nature of the cell, i.e., a polymer or liquid-based battery. Employing a polymer electrolyte imposes further criteria, as electrochemical stability of the backbone and sidechains becomes relevant [16, 17]. Many liquid solvents are available to use as electrolytes, each with a respective viscosity and dielectric constant that can be selected to facilitate the ionic conductivity. Typically, ethylene carbonate and dimethyl carbonate are used. In contrast, only a handful of lithium salts – lithium hexafluorophosphate ($LiPF_6$), lithium triflate ($LiSO_3CF_3$), lithium tetrafluoroborate ($LiBF_4$), lithium perfluorosulfonimide ($Li^+[CF_3SO_2NSO_2CF_3]^-$), among others – have been used for the electrolyte. Additionally, polyethylene oxide (PEO) has been the primary focus of polymer electrolytes. Despite this, details regarding the nature of salt-polymer interactions as well as the local structure of polymer electrolytes remain elusive. Ongoing research is focused on finding new, highly conductive salts with a large electrochemical operating window which dissolves in PEO at low temperature [18].

During charging and discharging, a small amount of the electrolyte separating the two electrodes decomposes, producing a film across the surface of the electrode materials. This film is referred to as the solid electrolyte interphase (SEI). The formation of an SEI is critical in the function and longevity of the battery–it is electrically insulating, which protects the remaining electrolyte from further decomposition, and allows for the diffusion of lithium during the discharging and charging processes. Ethylene carbonate (EC) is present in the overwhelming majority of commercially available electrolyte compositions, due to its ability to form this protective layer on the surface of graphite. In the event that the SEI cracks or flakes off, lithium dendrites could form which could lead to a "chemical short circuit." The end result would be the cell overheating causing flammability and, in the worst case scenario explosions. A thin passivating layer which has some degree of flexibility to expand and contract along with the anticipated volume changes of the electrodes upon intercalation and deintercalation is also desirable. While the capacity of a battery cell is primarily determined by the structure and electronic properties of the electrode materials, the longevity is intricately tied to the frequency of sidereactions that occur between the electrolyte and electrode. Control of the chemistry of this interface is of crucial importance to the longevity and performance of the battery [19].

To date, many of the decomposition products are not fully known. To complicate matters, SEI products depend on several variables, such as degree and rate of cycling, as well as temperature. However, it is well established that achieving a desired thickness of the insulating layers is essential to prolonging cell life and acquiring stable performance. As the thickness increases, the rate-determining step of the charge transfer reaction becomes the migration of the ion across the interphase. Irreversible capacity loss occurs when the lithium ions chemically bind to the components of the SEI or become trapped in the boundaries between SEI components, the layers become too electrically insulating, or if the thickness of the layer prevents lithium intercalation.

Overview of Experimental Techniques

Among the techniques that probe the average or long-range structure, powder X-ray diffraction (PXRD) and neutron diffraction (ND) will be briefly discussed. Techniques that provide local, atomistic information that will be mentioned are nuclear magnetic resonance (NMR) spectroscopy, X-ray photoelectron spectroscopy, X-ray absorption spectroscopy, and pair distribution function (PDF) analysis. A brief introduction to the underlying theory of each technique will be provided along with relevant examples to illustrate the type of information that can be extracted from each measurement. A particular emphasis will be placed in NMR spectroscopy and the various experiments that can be used to extract structural and dynamical information. The section will conclude with a few examples of the successes in first-principles calculations in determining the structure and properties of relevant materials.

Diffraction Methods

Two routine methods to determine the crystal structure, sample phase purity, estimations of atomic disorder, and grain size are through X-ray and neutron diffraction. Initially, these measurements could only be performed ex-situ for cycled battery samples. Currently, diffraction

patterns of relevant materials can be taken in-situ, as the battery is being cycled. Fundamentally, the techniques rely on the measurement of the intensity and angles of scattered X-rays or neutrons after the beams come in contact with a solid. X-ray diffractometers are readily available, allowing for the technique to be routine in the study of condensed matter. In contrast, neutron diffraction measurements require a special facility – either a spallation source or nuclear reactor.

The X-rays and neutrons scatter elastically in these diffraction experiments, meaning the energy of the incident and diffracted radiation is comparable. Bragg reflections occur when the incident and scattered waves of radiation interfere constructively in accordance with Bragg's law. Bragg's law describes the condition whereby you have constructive interference between successive atomic planes in a solid separated by an interlayer spacing d and is given by

$$n\lambda = 2d\sin(\theta), \tag{4}$$

where n is an integer greater than or equal to 1, and θ is the scattering angle. Atoms arranged periodically in a 3-D structure will impose selection rules on the type of reflections that are observed based on the symmetry of the crystal lattice. After considering the various symmetry operations possible in a 3-D arrangement of atoms, it is possible to classify all crystals into 1 of 230 so-called space groups. Additionally, one can define a unit cell, which contains atoms in the appropriate geometry that represents the simplest repeat unit of the crystal structure. The unit cell is parameterized by the lengths of the cell edges as well as the angles between them. The positions of the atoms inside the unit cell are given by a set of coordinates (x_i, y_i, z_i) measured from a specific lattice point known as the origin. Displacement parameters accompany the atomic positions to indicate anisotropic or spatially dependent positional disorder from thermal motions in the crystal. Information about the space group, unit cell parameters, and atomic positions uniquely identifies a material. Figure 1 shows in-situ diffraction patterns of the olivine compound $LiFePO_4$/C composite material collected by Myung et al. as a function of Li content [20]. As Li continues to be deintercalated, reflections due to a secondary $FePO_4$ phase appear, while the intensity of the $LiFePO_4$ reflections diminishes. By the end of the charge, $FePO_4$ becomes the major phase. As Li is introduced into the $FePO_4$ phase, the process is reversed, and the $LiFePO_4$ phase becomes dominant again. The reflections remain at the same 2θ, indicating that the lattice parameters are essentially constant upon cycling, in sharp contrast to the lithium transition metal (Co, Ni, Mn) oxide materials.

One of the main differences between X-ray and neutron diffraction is that X-rays scatter from the electron density of atoms within the crystal, whereas neutrons scatter from atomic nuclei. This implies that heavier elements, those with a larger atomic number, scatter and absorb the X-rays more effectively, making it difficult to detect light elements like lithium. A second implication is that contrast between neighboring elements in the periodic table or two different elements whose oxidations states produce the same electronic configuration will be poor. Neutrons posses spin, which can interact with the magnetic moment of electrons leading to so-called magnetic scattering. In this manner, so-called magnetic reflections can appear in the diffraction pattern, which aid in elucidating the magnetic structure of materials. Unlike X-rays, the neutron-scattering length does not vary in a systematic manner. Consequently, neutrons may diffract relatively strongly with light elements. Additionally, adjacent elements, which would be difficult to discern through X-ray diffraction experiments, may possess nuclear scattering properties that allow for their identification. A relevant example of this contrast is between Fe and Co. An added benefit of neutrons over X-rays is that relatively few elements, or more precisely isotopes, have significant absorption cross-sections. Since neutrons scatter from the nucleus, there is a significant dependence of the diffracted intensity on the particular isotope of the element. The sensitivity of the technique to different isotopes offers the possibility of performing a null scattering experiment, where a specific ratio of two isotopes is chosen, having neutron-scattering lengths of opposite sign, that effectively cancels the contribution of the element to the diffracted intensity.

In X-ray diffraction, the intensity of the diffracted beam I_{hkl} is proportional to the so-called structure factor F_{hkl} given by

$$F_{hkl} = \sum_{n=1}^{N} f_n e^{2\pi i(hx+ky+lz)}, \tag{5}$$

Lithium Ion Batteries, Electrochemical Reactions in. Figure 1
In-situ X-ray diffraction patterns of $Li_{1-\delta}FePO_4$ as a function of lithium content δ (From [20])

where f_n is the scattering factor for atom n within the unit cell (repeat unit of the crystal), and h, k, l are the Miller indices, which describe the virtual planes of atoms in a crystal lattice. For neutron diffraction, a similar expression is obtained for the structure factor, with the exception that the neutron-scattering factor b replaces f. The nuclei of atoms act as pin-point scatterers, unlike the electron clouds which have a finite size relative to the wavelengths of the radiation used in the experiment. The parameter b is independent of the scattering angle, in sharp contrast to f in the analogous X-ray expression which decreases with increasing angle. Thus, d-spacings, atomic positions, and their corresponding thermal parameters are more precisely determined through powder neutron diffraction. A breakthrough in structure analysis using diffraction

techniques was realized with the Rietveld method [21] which allowed the full profile of the diffraction pattern to be refined according to a specific structural model.

One method that is becoming increasingly useful in the study of solid, disordered materials is pair distribution function (PDF) analysis. The PDF can be understood as the distribution of bond lengths in a sample, weighted by the scattering power of the contributing atoms. It provides the probability of finding an atom at a distance r from another atom. The PDF is obtained from the sine Fourier transform of the total scattering pattern $S(Q)$, which includes both the Bragg and diffuse scattering, of a sample. Formally, this is given by

$$\begin{aligned} G(r) &= 4\pi r[\rho(r) - \rho_0] \\ &= \frac{2}{\pi}\int_0^\infty Q[S(Q) - 1]\sin(Qr)dQ, \end{aligned} \tag{6}$$

where $\rho(r)$ is the microscopic pair density, ρ_0 is the average number density, and Q is the magnitude of the scattering vector. For elastic scattering, $Q = 4\pi\sin(\theta)/\lambda$ with 2θ being the scattering angle and λ being the wavelength of the radiation used. A data plot includes $G(r)$ as a function of distance in angstroms. Since data cannot be collected to infinite Q, the real-space resolution of the PDF is decreased; Fourier transformation at a finite Q yields artifacts known as termination ripples. Additionally, the Q resolution results in an exponential dampening of peaks in the PDF with increasing r. As a result, it is desirable to perform experiments at high energy neutron or synchrotron X-ray sources to access high values of Q_{max} in order to enhance resolution. An added benefit of neutron PDF studies is that isotopic substitution can provide chemically specific pair distribution functions. For a sample containing two atoms of interest, say A and B, independent measurements can provide A–A, A–B, and B–B pairwise correlations.

Several analyses are available after obtaining an experimental PDF. Among these are bond length information and coordination number of atoms through a simple fit of the data. Peak widths can provide information regarding bond length distributions or correlated motions of atoms. PDFs are also used to refine or compare structural models of materials at the local- and medium-range length scales. Given a specific structural model, a calculated PDF, $G_c(r)$ is given by,

$$G_c(r) = \frac{1}{r}\sum_i\sum_j\left[\frac{b_i b_j}{\langle b\rangle^2}\delta(r - r_{ij})\right] - 4\pi r\rho_0, \tag{7}$$

where the sum extends over all ij atom pairs in the model crystal separated by an internuclear distance r_{ij}, b_i is the scattering power of atom i, and $\langle b\rangle$ is the average scattering power of the sample. For neutron scattering, b_i is the neutron-scattering length; for X-rays, it is the atomic form factor evaluated for a given Q. At $Q = 0$, the value of b_i in the X-ray scattering case is the number of electrons in the i atom. To model the finite Q in the data, a Q-dependent termination function of the form $\sin(Q_{max}r/r)$ is convoluted with the calculated PDF $G_c(r)$. An exponential damping function can also be multiplied to mimic the loss of resolution in reciprocal space.

A few methods are available for a full profile refinement of the PDF obtained from a structural model. Structural parameters such as lattice constants, atomic positions, atomic displacement parameters, and site occupancies can be refined over a distance r using the program PDFFIT [22]. The program works well in instances where the model structure can be defined with a relatively small number of atoms. For more complex cases, in which many atoms are needed to match a structural model, the Reverse Monte Carlo (RMC) [23] technique can be employed. This algorithm involves the calculation of the PDF from a specific crystal configuration and a corresponding "goodness-of-fit" parameter χ^2 given by,

$$\chi^2 = \sum_{i=1}^{N}\frac{[G_e(r_i) - G_c(r_i)]^2}{\sigma^2} \tag{8}$$

where G_e and G_c are the experimental and calculated PDFs, respectively, and σ is a weighting factor corresponding to experimental uncertainty. The best calculation is that which produces a χ^2 minimum. The algorithm proceeds to a random selection of an atom in the model crystal. The occupancy or displacement of the atom is changed by a random amount. The new PDF and χ^2 are subsequently recalculated, along with the change in the agreement factor $\Delta\chi^2$. If the change made lowers χ^2, then the change is accepted.

On the other hand, if the change increases χ^2 by $\Delta\chi^2$, it is not automatically rejected but accepted with a probability of $P = \exp(-\Delta\chi^2/2)$. This formalism ultimately ensures that the structural model does not get trapped in a local minimum, but converges to a global minimum. An RMC simulation serves to maximize the amount of disorder (entropy) in the atomic configuration while maintaining an agreement with experimental data. It is important to emphasize that this method can produce a range of atomic configurations, each with varying degrees of disorder that are consistent with experimentally obtained PDFs. Therefore, it is essential to have complementary information from other techniques which can place constraints on both local- and long-range structures to minimize the number of plausible configurations.

X-Ray Photoelectron Spectroscopy

X-ray photoelectron spectroscopy (XPS) is a quantitative technique which measures the number and kinetic energy of photoelectrons emitted from a sample that was irradiated with X-ray radiation. It is routinely used to determine the surface elemental composition or empirical formula of materials. XPS requires ultrahigh vacuum (UHV) conditions, on the order of $<10^{-9}$ torr, in order to detect the emitted electrons and minimize contamination or side reactions on the surface of the material. The spectrum involves a plot of electron count versus electron binding energy. The binding energy of electrons is specific to the element, so that peaks in the spectrum occur at characteristic energies corresponding to the electron configuration in a specific chemical bonding arrangement. Two peaks, with various integrated intensity ratios, are observed for electrons residing in *p*, *d*, or *f* orbitals. The separation of the two peaks, known as spin-orbit coupling, and their relative intensity assist in the identification of the elements in the sample. This is due to the fact that these values are characteristic and approximately constant for a core level of a given element, irrespective of the compound.

Variations in the binding energy of a core electron for an element, although small (on the order of a few electron volts eV), are still measureable and form the basis of the determination of the chemical speciation of a particular element, i.e., the bonding arrangement, type of nearest neighbors, and oxidation state. Briefly, the binding energy of an electron is determined primarily by the magnitude of the electrostatic interaction between itself and the nucleus. This interaction strength can be modulated by electrostatic shielding effects from other electrons, which in turn can depend on the removal or addition of charge brought about by chemical bonding. Removal of valence electron charge from an element (oxidation) results in an increase in binding energy; addition lowers the binding energy. This sensitivity to chemical speciation is demonstrated using the results from Dedryvère et al. (see Fig. 2), who studied various organic and inorganic decomposition products of the SEI in a CoO battery [24]. Peaks corresponding to C–C, C–O, O–C═O, and O_2C═O were clearly identified. Given quantitative information about the different carbon local environments, decomposition mechanisms that form the constituents of the SEI can be proposed.

The photoemission process that forms the basis of an XPS measurement can be deconstructed into three basic steps: (1) photon absorption and ionization, (2) atomic response with the generation of a photoelectron, and (3) transport of the ejected electron to the surface. These three steps are often labeled initial state, final state, and extrinsic state respectively. The intensity of an electron emitted at a depth d from the surface of material will be attenuated according to the Beer-Lambert Law. One can define the sampling depth as the minimum distance from the surface in which 95% of all the emitted photoelectrons are scattered. This parameter is intimately tied to the inelastic mean free path of an electron in a solid. The mean free path depends on the kinetic energy of the photoelectron and sample studied. For XPS, typical sampling depths are on the order of a few nanometers, rendering the technique most useful for thin films and surface studies. Composition-depth profiling can be performed by combining XPS with Ar^+ ion sputtering to study species away from the surface. In interpreting the results of XPS depth profiling, it is essential to consider two important factors that can affect the results: (1) the sputtering efficiency is dependent on the type of material being investigated – usually lower for stable inorganic solids and higher for organic matter, and (2) sputtering will induce surface chemical reactions and sample decomposition.

Lithium Ion Batteries, Electrochemical Reactions in. Figure 2
Carbon 1*s* XPS spectra of the first charge/discharge cycle of CoO reacting with Li in a CoO-liquid electrolyte-Li metal electrochemical cell: (**a**) starting CoO powder, (**b**) after insertion of 1 Li per mole ($x = 1$), (**c**) after total discharge at 0.02 V, (**d**) after charge at 1.8 V, and (**e**) after charge at 3.0 V, from [24]. The assignments of the peaks are shown at the *top* of the figure

Quantitative measurements of an element ($\sim \pm 10\%$) can be made by relating the intensity of a specific peak "p" for an element "i" (I_i) using the relation:

$$I_i = CN_i\sigma_i\lambda_i \tag{9}$$

where C represents a constant which captures instrumental factors related to the signal acquisition, N_i is the atomic concentration of element "i," σ_i is the photoelectron cross-section for the element "i" expressed by peak "p" (commonly referred to as the Scofield factor), and λ_i is the inelastic mean free path of a photoelectron emitted by element "i" as expressed by peak "p."

X-Ray Absorption Spectroscopy

X-ray absorption spectroscopy (XAS) is performed using synchrotron radiation sources, where the X-ray energies are tunable and the intensity is large. XAS measurements of transition metals are most often performed at convenient energy ranges, i.e., without the use of ultrahigh vacuum conditions, although a notable exception includes the study of the oxygen K-edge in a lithium cobalt oxide-based cell [25]. The technique is involves tuning the incident X-ray radiation to excite core electrons of a specific element. The primary use of this absorption spectroscopy in battery science is to determine the oxidation state of a metal and bonding configuration between the metal of interest and the nearest neighboring ions or molecules, oftentimes referred to as ligands. Bonding between metals and ligands vary in degrees of covalency, a measure of how electron density is shared among atoms.

The energy profile of a sample depends on several factors: the element, the oxidation state of the element, the specific atomic orbital in which the electron resides, as well as the geometry and strength of the bonding to ligands. Depending on the type of core electron that is excited, the energy is given a specific label, called an "edge." The principal quantum numbers, $n = 1, 2, 3$, correspond to the K-, M-, and L-edges, respectively [26].

An XAS spectrum consists of normalized absorption plotted against the incident energy of the X-ray radiation. There are three main features to the absorption plot. The most prominent feature is called the "rising edge" and corresponds to a pronounced increase in absorption arising from 1*s* to *p* electronic transitions. A second region, known as the "pre-edge," occurs at slightly lower energies with respect to the rising edge. The pre-edge features arise from weak transitions between electrons in 1*s* and *d* atomic orbitals. Spectroscopy using energies in the pre-edge and rising edge regions is often called X-ray absorption

near edge structure (XANES) or near-edge X-ray absorption fine structure (NEXAFS). The third region occurs at higher energies from the rising edge and is referred to as extended X-ray absorption fine structure (EXAFS). The EXAFS region is characterized by oscillations that arise from backscattering events that modulate the amplitude and wavelength of the ejected photoelectron from the source atom. Both the type of neighboring atoms and their distance to the source of the ejected photoelectron affect the degree of backscattering, so that bonding geometry and local coordination chemistry of the sample can be elucidated.

Given a homogeneous sample with a uniform thickness x, the absorption coefficient $\mu(E)$ can be related to the intensity of the incident (I_0) and transmitted (I) radiation using

$$\frac{I}{I_0} = e^{-\mu(E)x} \tag{10}$$

XAS can measure either transmission or fluorescence. The absorption coefficient is typically a smooth function of the energy of the radiation E, with the exception of the behavior at the absorption edge of a particular element. $\mu(E)$ can be approximated by

$$\mu(E) \approx \frac{\rho Z^4}{ME^3}, \tag{11}$$

where ρ is the density of the sample, Z is the atomic number of the element, and M is the corresponding atomic mass.

However, the true power and utility of the technique lies in the fact that the total absorption of the sample is not a simple summation of the atomic absorption coefficients, but is strongly affected by the neighboring atoms – a phenomenon particularly relevant in the EXAFS region. One can express the total absorption coefficient $\mu(E)$ as the absorption coefficient of an isolated atom $\mu_0(E)$ multiplied by a correction factor χ such that $\mu = \mu_0(1 + \chi)$. The parameter χ can be thought of as the fractional change in absorption coefficient induced by the neighboring atoms. In the single scattering approximation, Sayers et al. have introduced [27] an expression for χ – what is now known as the standard EXAFS equation:

$$\chi(k) = \sum_j \frac{N_j f_j(k) e^{-2k^2\sigma_j^2}}{kr_j^2} \sin\left[2kr_j + \delta_j(k)\right] \tag{12}$$

where k is the wave number of the photoelectron ($k = \sqrt{\frac{2m(E-E_0)}{\hbar^2}}$, E is the energy of the electron, E_0 is the absorption edge energy, m is the mass of the electron), N_j is the number of j atoms surrounding the element under investigation, r_j is the distance from the observed element to the nearest neighbors, σ_j^2 is a measure of the disorder in the distance to neighboring j atoms, $f(k)$ is the scattering amplitude of the wave and $\delta_j(k)$ is the corresponding phase shift. In essence, by simply measuring the scattered amplitude and phase shift, the number of neighboring atoms, and their distance, a measure of the atomic disorder can be estimated. Moreover, EXAFS will be sensitive to the type of neighboring element since the scattering amplitude depends on Z.

Figure 3a displays the normalized Ni K-edge absorbance spectrum of $Li_{1-x}Ni_{1/3}Co_{1/3}Mn_{1/3}O_2$ as a function of lithium content as performed by Tsai et al. [28]. Figure 3b shows the corresponding second derivative absorbance. Similar measurements can be made at the Co and Mn K-edges. The energy position of the pre-edge and absorption edge peaks of $LiNi_{1/3}Co_{1/3}Mn_{1/3}O_2$ are similar to those found in the reference compound NiO, consistent with the presence of Ni^{2+} in the pristine material. During delithiation, these peaks shift gradually to higher energies and eventually surpassing the energy position of the absorption edge of $LiNiO_2$ starting at the composition $Li_{0.15}Ni_{1/3}Co_{1/3}Mn_{1/3}O_2$, implying the existence of Ni^{4+} cations. During lithiation, these peaks shift to their original energy positions, indicating that during charging and discharging either a two-step (Ni^{2+}/Ni^{3+} followed by Ni^{3+}/Ni^{4+}) or single step (Ni^{2+}/Ni^{4+}) redox pair reaction with Ni occurs.

The authors then proceeded to analyze the corresponding EXAFS data. The k^2-weighted Fourier transformed spectra of the Ni K-edge of $Li_{1-x}Ni_{1/3}Co_{1/3}Mn_{1/3}O_2$ as a function of x is shown in Fig. 4. A total of four peaks are observed in each sample, which were ascribed to single and multiple scattering events. The first peak at ~1.5 Å is assigned to the shortest Ni-O distance in the octahedral site occupied by Ni. The second peak at ~2.5 Å describes the distance

Lithium Ion Batteries, Electrochemical Reactions in. Figure 3

(**a**) Normalized in situ absorbance and (**b**) second derivative absorbance of Ni K-edge for $Li_{1-x}Ni_{1/3}Co_{1/3}Mn_{1/3}O_2$ as a function of Li content *x*. The plots for $LiNiO_2$ and NiO are also presented to provide reference spectra for Ni^{3+} and Ni^{2+} local environments respectively (From [27])

from Ni to the nearest Ni/Co/Mn in the transition metal layer. The weak peak at 4.5 Å is dominated by combined effects of six metal-metal scattering within the transition metal layer, and six metal-metal scattering from two adjacent transition metal layers. The second weak peak at ~5.3 Å is attributed to a focusing effect of 12 collinear multiple metal-metal-metal scattering events, where a second scatterer lies in between the emitting atom and another scatterer. During delithiation of the pristine material the Ni-O decreases, consistent with the electroactivity of the Ni sites. Additionally, the two-step reaction mechanism proposed earlier was also confirmed, since the trends in the experimentally determined Ni-O distances as a function of Li content could not be explained without the incorporation of Ni^{3+}. The differences in bond length are consequence of the various sizes of the Ni^{2+}, Ni^{3+}, and Ni^{4+} cations.

NMR Spectroscopy

Over the years, numerous materials have been investigated as potential electrodes in new generation Li-ion batteries using nuclear magnetic resonance (NMR) spectroscopy [29]. The primary nucleus of investigation for the electrode materials has been lithium. However, any nucleus possessing spin can potentially be studied, such as ^{31}P, ^{51}V, ^{13}C, ^{1}H, ^{19}F, etc. There are two spin-active isotopes of lithium which can be observed using NMR techniques – ^{6}Li and ^{7}Li. The natural abundance of ^{7}Li is approximately 92.41%, while that of ^{6}Li is 7.59%. The gyromagnetic ratio γ, in units $10^7 \mathrm{rad T^{-1} s^{-1}}$, of ^{7}Li and ^{6}Li is 10.40 and 3.94, respectively. Both nuclei are quadrupoles, with spin $I > ½$ ($I = 1$ and $I = 3/2$ for ^{6}Li and ^{7}Li, respectively), and are affected by the quadrupole interaction. The quadrupole moment of ^{7}Li is significantly larger than that of ^{6}Li. Consequently, the effects of the quadrupole interaction are more pronounced in ^{7}Li spectra. The interaction is anisotropic and produces characteristic broadening and line shapes in the static and magic angle–spinning (MAS) spectra, which reflect the local site symmetry of the lithium ion. If sample spinning speeds do not exceed the static line width of the spectra, a series of peaks, termed spinning sidebands, can be observed from the satellite transitions ($\pm\frac{3}{2} \leftrightarrow \pm\frac{1}{2}$) and to a lesser extent, the magnetic dipole broadened central transition ($+\frac{1}{2} \leftrightarrow -\frac{1}{2}$). The chemical shift range of lithium in diamagnetic compounds is relatively small, which may hinder the identification of chemically distinct sites. In contrast, the Li spectra of materials for Li-ion batteries, particularly the paramagnetic transition metal oxide cathode materials, are dominated by interactions involving the nucleus and the electronic spins.

The nucleus can interact with the unpaired electron spins of a nearby paramagnet through hyperfine interactions or with electrons in the conduction band of materials, the latter referred to as the Knight shift. These interactions can lead to significant peak broadening and shifts of the resonances. Nevertheless, these interactions contain information about the electronic structure and local environment of the Li atoms and can be theoretically used to track changes in each contribution upon cycling.

The observed NMR shift, expressed as $\Delta\omega/\omega_0$, induced by the Fermi contact hyperfine interaction in materials containing 3*d*-transition metals is proportional to the unpaired electron spin density at the nucleus site. The magnitude of the interaction is directly proportional to the Fermi constant A_c and the time-averaged electron spin $\langle S_z \rangle$ by

$$\frac{\Delta\omega}{\omega_0} = -\frac{A_c}{\omega_0 \hbar}\langle S_z \rangle \tag{13}$$

The term $\langle S_Z \rangle$ can be expressed as

$$\langle S_Z \rangle = -\frac{B_0}{\mu_0 g N_A \mu_B}\chi_M \tag{14}$$

where B_0 is the strength of the external magnetic field, χ_M is the molar susceptibility, μ_0 is the permeability of

free space, g is the g-factor of the electron, N_A is Avogadro's number, and μ_B is the Bohr magneton.

The Fermi constant is a measure of the amount of spin density that is present at the site of interest, which in this case is the Li ion. The constant also determine the direction of the shift, i.e., whether it is positive or negative. The time average of the electron spin of the paramagnetic ion is of importance since at ambient temperatures, in systems that can be studied by nuclear magnetic resonance spectroscopy, the relaxation of the electrons occurs many orders of magnitude faster than the coupling frequency A_c/h. The formalism presented is strictly true for systems where the orbital angular momentum is sufficiently suppressed so that the magnetic moments could be reasonably calculated using the "spin-only" contributions. For transition metal ions found in battery materials, this is usually a reasonable approximation. The Fermi contact shift in many materials has been found to be additive, so that the total observed shift arises from the summation of individual shift contributions induced by each paramagnetic ion. In this manner, shift scales can be created for the Li ion in different environments using the shifts of model compounds. This scale can then be used to make tentative assignments of Li spectra in battery materials. Figure 5 shows a Li shift scale for Mn-containing compounds compiled by Grey et al. [30].

The Li atoms in $LiMO_2$ (M = Co, Cr, Fe, Mn, Ni) phases, and their respective solid solutions, may interact with transition metal ions in the first and second cation coordination shells. These interactions are termed the 90° and 180° interactions, respectively, and are named according to the angle of the M–O–Li bond. In the discussion of the shift mechanisms, the labeling conventions used by Carlier et al. will be employed [31]. The $3d$ atomic orbitals of a metal in an ideal octahedral site are labeled t_{2g} and e_g. The $2p$ oxygen valence orbitals will be labeled p_σ and p_π,

Lithium Ion Batteries, Electrochemical Reactions in. Figure 5
Lithium hyperfine shifts observed in model Mn-containing compounds for four-coordinate and six-coordinate lithium environments (From [29])

depending on the type of overlap between the oxygen and M $3d$ orbitals. If electron density is present along the O-M internuclear axis, it is labeled p_σ. If electron density lies above and below the O-M internuclear axis, the O $2p$ valence orbital is labeled p_π. The Li valence atomic orbital is labeled s. Overlap of the M e_g, O $2p$ and Li s atomic orbitals leads to a bonding and antibonding molecular orbital, e_g-p_σ-s and e_g^*-p_σ -s respectively. The bonding orbital has a large contribution from the oxygen, while the antibonding orbital has a significant contribution from the metal. The M t_{2g} atomic orbitals are nonbonding to a first approximation, though Fermi contact shifts in some materials cannot be explained without mixing of these orbitals with Li s.

The spin transfer from the metal to the Li occurs via two concurrent mechanisms – spin delocalization and spin polarization (see Fig. 6). In the spin delocalization mechanism, the Li, O, and M atomic orbitals of appropriate symmetry overlap in the lattice. Consequently, a positive spin polarization is maintained along M–O–Li, so that the spin transferred from the metal to the lithium ion is aligned with the external magnetic field. The spin polarization mechanism relies on the quantum mechanical effect known as the exchange interaction, which causes unpaired electrons in a metal orbital to polarize the electrons in the other doubly occupied $3d$ orbitals. Thus an electron with the *same* spin as the unpaired electron in a second nonequivalent transition metal orbital is present at the metal site rather than an electron with the opposite spin. Positive spin density increases on the transition metal site while negative spin density is transferred to the oxygen and lithium orbitals.

Lithium Ion Batteries, Electrochemical Reactions in. Figure 6
Schematic of the two principle mechanisms of the Fermi contact interaction governing the observed Li shifts in battery materials for both 90° and 180° geometries between the Li nucleus and the paramagnetic transition metal, from [30]. See text for details

The observed ^{6,7}Li shifts depend on the total transfer of spin density to the Li atom by these two mechanisms for every transition metal in the sample. In general, the delocalization mechanism induces larger shifts than the polarization mechanism. However, the geometry of the system must be considered since Jahn-Teller distortions of the MO_6 octahedral units remove the degeneracy of the e_g orbitals, for example, and affect the orbitals involved and the amount of spin density transferred. Since $\langle S_z \rangle$ is proportional to $B_0\chi_M$, the Fermi contact interaction and the magnetic susceptibility of a material should display the same temperature behavior. If the magnetic susceptibility of a material exhibits Curie-Weiss behavior, then it follows that the lithium shift will be inversely proportional to temperature.

The Knight shift results from the interaction of a nuclear spin with the electrons in the conduction band of the material. This shift is often much larger than the chemical shift observed in diamagnetic compounds. For the most part, the frequency shift ($\Delta\omega$) is positive, and the fractional shift, defined as $\Delta\omega/\omega_D$ (where ω_D is the frequency of the metal in a diamagnetic compound) has the following properties: (1) at different magnetic fields, $\Delta\omega/\omega_D$ is constant, (2) the fractional shift is nearly independent of temperature, and (3) the fractional shift generally increases with increasing nuclear charge. Figure 7 shows a series of static in situ ^{7}Li NMR spectra of lithium inserting into disordered carbon in an assembled battery from Letellier and co workers [32]. The initial spectrum is characterized by two peaks – an intense and relatively narrow resonance at approximately −2 ppm arising from diamagnetic lithium in the electrolyte ($LiPF_6$) and SEI, and a second broad resonance at 263 ppm arising from metallic lithium used as the anode. A series of relatively weak and broad resonances appear during cycling of the battery, corresponding to various amounts of lithium inserting into the disordered carbon. These resonances vary smoothly during the charge and discharge cycles. The shifts of the Li metal and the various Li_xC_y compounds, each of which contains varying degrees of metallic character, from the diamagnetic 0 ppm region are due to the Knight shift effects.

NMR spectroscopy is very sensitive to a wide timescale – on the order of seconds to nanoseconds.

Lithium Ion Batteries, Electrochemical Reactions in. Figure 7
In situ static ^{7}Li NMR of a disordered carbon-Li metal battery cell taken over three charge and discharge cycles. Peaks at ~0 ppm and 260 ppm correspond to lithium in the electrolyte/SEI and Li metal anode respectively. Resonances in the range of 0–140 ppm are assigned to Li environments inserted into the disordered carbon (From [31])

An accurate mathematical treatment of motional averaging in NMR spectroscopy is highly dependent on the relative timescale of the motional process, with respect to the Larmor time scale (the reciprocal of the NMR frequency), since nonsecular Hamiltonian terms (i.e., those that do not commute with the Hamiltonian) are mainly responsible for relaxation. Motional processes that are faster than the Larmor timescale, such as vibrations or librations, average the spin Hamiltonians *before* the secular approximation is made. Motion that is slower than the Larmor timescale, such as rotations and translations, average the spin Hamiltonian *after* the secular approximation has been made.

After the application of a radiofrequency pulse, which manipulates the nuclear magnetization, the spins begin to preferentially align with the external,

static magnetic field, or to state it differently – the populations of spins in the different spin-states reach thermal equilibrium. Three relaxation times are typically measured: (1) the spin-lattice or longitudinal relaxation (T_1), (2) spin-spin or transverse relaxation (T_2), and (3) the relaxation in the rotating frame ($T_{1\rho}$). The rotating frame is a coordinate system which rotates about the z-axis (the direction of the static external magnetic field B_0) at the Larmor frequency of the nucleus under observation. This frame of reference is used to simplify the analysis of the trajectory of nuclear spin magnetization.

The T_1 relaxation refers to the time it takes for the z-component of the magnetization M_z to achieve an equilibrium value M_0. Two different equations could be used to extract T_1 from a series of measurements, depending on whether a saturation-recovery experiment or an inversion recovery experiment (explained in the subsequent section) is used. In the former case, the following equation is used:

$$M_z(t) = M_0\left(1 - e^{-\frac{t}{T_1}}\right) \tag{15}$$

For an inversion recovery experiment, the equation changes slightly to,

$$M_z(t) = M_0\left(1 - 2e^{-\frac{t}{T_1}}\right) \tag{16}$$

The T_2 relaxation time refers to the return of the observable, transverse (xy-plane) magnetization M_{xy} to an equilibrium value. This process could be modeled by a simple exponential

$$M_{xy}(t) = M_{xy0}e^{-\frac{t}{T_2}} \tag{17}$$

Two factors influence the loss of transverse magnetization – magnetic, molecular interactions and inhomogeneity in magnetic field. The observed decay in transverse magnetization is thus a combination of these two effects.

Both spin-lattice and spin-spin relaxation occur simultaneously, with $T_2 \leq T_1$ in the majority of cases. In heterogeneous samples, there are often multiple T_1 and T_2 relaxation times due, in part, to the presence of many local environments. $T_{1\rho}$ magnetization decay can be modeled as a single exponential much like T_2, but oftentimes, the behavior is more complex. Spin-lattice relaxation, evidenced by changes in the characteristic time T_1, occurs when motion is on the Larmor time scale. On the spectral timescale, typically on the order of μs to ms, line shapes of a spectrum are greatly affected, resulting in either line broadening or narrowing. Processes that are relatively very slow – millisecond to second timescales – do not result in line-shape changes. However, they can still be detected by observing their effect on the dynamics of longitudinal magnetization, specifically using a two-dimensional (2-D) exchange experiment [33].

To illustrate the line-shape changes occurring for motion on the spectrum timescale, a two-site symmetrical exchange will be considered. A nuclear spin is transported from site A to site B and back again at a rate k, i.e., A → B and B → A both occur at a rate k. The two sites occur with equal probability, and the exchange is fast enough so that no intermediate chemical states are considered. The two different chemical environments induce two chemical shifts. The angular chemical shift frequencies of the two sites are expressed as ω_A and ω_B for sites A and B, respectively. If the rate constant k is the same order of magnitude as the angular chemical shift frequency, i.e., $k = \omega_{diff} = \omega_A - \omega_B$, the line shapes will change drastically. Under these circumstances, the system is referred to as being in the intermediate exchange regime.

Within this intermediate exchange regime, one can define three regions – the crossover point, slow intermediate exchange, and the fast intermediate exchange regimes. The crossover point occurs when $k = |\omega_{diff}/2|$. For slow and fast intermediate exchange, $k < |\omega_{diff}/2|$ and $k > |\omega_{diff}/2|$, respectively. In the slow intermediate exchange regime, as one approaches the crossover point, motional broadening occurs. In the two-site symmetric exchange example, this would result in broadening of the two peaks along with coalescence as k increases to the crossover point. At the crossover point, a single broad resonance will be present at the average of the two chemical shifts. As k increases past the crossover point to the fast intermediate exchange regime, the line width of the single resonance is reduced – a phenomenon known as motional narrowing. Motional narrowing in this regime occurs because the spins jump so frequently between the two sites, that no significant phase difference in the transverse magnetization is accumulated as a result of the different local environments. The spin experiences

a well-defined average precession frequency, so that the coalesced peak continues to narrow [33].

In ideal cases, the temperature dependent rate constants $k(T)$ display Arrhenius behavior such that the data could be fitted with,

$$k(T) = C\exp(-E_A/(N_A k_B T)) \tag{18}$$

where C is a constant, E_A is the activation energy of the jump, N_A is Avogadro's number, k_B is Boltzmann's constant and T is temperature. For an asymmetric two site exchange, where the rates of A → B and B → A are different, similar phenomena occur, with the exception that in the fast intermediate exchange limit, the coalesced peak is positioned at the average of the chemical shift of the original two peaks, weighted by the equilibrium concentrations of the two species.

Another advantage of NMR spectroscopy is the ability to measure self-diffusion coefficients. Diffusion measurements are overwhelmingly made in the study of liquid electrolytes. The basic principle of the experiment lies in the fact that nuclear spins placed in a nonuniform magnetic field will experience different local fields depending on their spatial location. Differences in the strength of local magnetic fields will induce slightly different procession frequencies of the nuclear spin under investigation.

When a simple Hahn-echo pulse sequence is applied to the sample in a non-uniform magnetic field, the presence of motion can be inferred by the echo signal intensity taken as a function of a delay. If a spin has not diffused, it will have a constant precession frequency so that at the end of the dephasing period 2τ, the spin magnetization is said to have been completely refocused. If a spin moves along a magnetic field gradient the precession frequency will change, resulting in an attenuated echo intensity at 2τ. By performing a series of experiments where τ is varied, the reduced intensity of the resonance could be used to calculate the diffusion coefficient of the nucleus using the equation [34],

$$M(2\tau) = M_0 e^{\frac{2\tau}{T_2}} e^{-\frac{2}{3}\left(\gamma\frac{\delta H}{\delta Z}\right)^2 D\tau^3} \tag{19}$$

where M_0 is some initial magnetization, T_2 is the spin-spin relaxation time, γ is the gyromagnetic ratio of the nucleus under investigation, $(\delta H/\delta Z)$ is the magnetic field gradient, and D is the diffusion coefficient. In the limit where $\tau << T_2$, the reduction of the echo signal intensity is dominated by the diffusion process. In samples with short T_2 values, it is difficult to separate the effects of spin-spin relaxation and diffusion in the attenuation of the echo signal.

These spin-echo experiments are most commonly performed using pulse field gradients, introduced by Stejskal and Tanner [35], or using the so-called "static fringe-field method" [36, 37]. In general, T_2 times greater than 2 ms for each species is required to perform the diffusion measurements and extract precise diffusion coefficients. Pulse-field gradient spin-echo methods require special amplifiers which control the strength, duration, and time interval between gradient pulses. The gradients that can be implemented typically range from 10 to 70 mT/cm. In this experiment, the delay between the Hahn-echo pulses is kept constant, so that the contribution of T_2 relaxation on the attenuation of the echo signal intensity is constant. Since the experiment is performed in the "sweet spot" of the magnet, where the magnetic field is the most homogenous, the spectral resolution is relatively high. The fringe-field method requires the probe to be positioned outside of the sweet spot of the magnet, where large static magnetic field gradients are present – typically greater than 100 mT/cm. The relatively large gradients allow relatively small diffusion coefficients to be measured, usually less than 10^{-12} m^2/s. Unfortunately, the line widths of the resonances are significantly large due to inhomogenous line broadening. Consequently, the sensitivity and resolution decreases. Additionally, the T_2 of the chemical species must be measured independently in a uniform magnetic field.

Conductivity and ionic diffusion could be related using the modified Nernst-Einstein equation

$$\sigma_{calc} = \frac{Nq^2(D_{Li} + D_{an})\alpha}{kT} \tag{20}$$

where σ_{calc} is the calculated ionic conductivity, N is the number of ions per unit volume, q is the charge of the ions, D_{Li} and D_{an} are the diffusion coefficients of the lithium ion and anion respectively, a is the degree of dissociation, k is Boltzmann's constant, and T is temperature. In many instances, the calculated conductivities using the measured diffusion coefficients from pulse-field gradient NMR are much higher than values measured directly [38–43]. The discrepancy could arise

from the differences in the migration distance probed using the two different techniques. Moreover, electrical conductivity detects the motion of charged ions, without discrimination of element or sign of the charge. Diffusion coefficients contain contributions from ions in both charge-neutral and dissociated species of a particular probe nucleus.

The measurement of diffusion coefficients is particularly important in polymer electrolyte research. One of the desired properties of a potential electrolyte material is the selective mobility of the Li^+ cation. Numerous strategies have been implemented to attain this property [1, 44, 45]. One method of quantifying the selective mobility is the calculation of transference numbers, which is the fraction of the total electric current that the anions and cations carry while passing through an electrolyte. Using the notation of Kalita et al. [46], the transference number for lithium, t^+, could be expressed as,

$$t^+ = \frac{D^+}{D^+ + D^-} \tag{21}$$

where D^+ and D^- are the cations and anion diffusion coefficients respectively. As implied above, determining the transference number for free Li^+ is not straightforward using NMR or electrical conductivity measurements.

Computational Methods

Computational methods have advanced significantly over the past few years, allowing for the accurate prediction and explanation of various properties of materials relevant to the battery field, including lithium and electron mobilities [47–49], voltage profiles [50–53], average insertion potentials [50, 54–58], and phase stabilities [59–61], using first-principles calculations. A few methods are available for first-principles calculations of electronic structure – Hartree-Fock, Møller-Plesset Perturbation theory, highly correlated methods, and density functional theory. Typical basis sets used for these calculations include Slater-type functions ($Y_l^m \mathrm{r}^{n-1} \exp(-\xi r/\mathrm{a}_0)$), Gaussian-type functions ($Y_l^m \exp(-(\alpha r)^2)$), or plane waves ($\exp(ig \cdot r)$), where Y_l^m denotes the spherical harmonics and r is the radial distance of the electron from the nucleus. The formalism within which many of these calculations are conducted in condensed matter is typically density functional theory (DFT), using plane waves and pseudopotentials. The intricate details of the theory are beyond the scope of this article. For the purposes of this discussion, it is sufficient to understand DFT as a reformulation of many-body quantum mechanics in terms of the probability density rather than the wave function. Specifically, it is used to investigate the electronic structure of condensed phases using functionals, i.e., functions of another function. The primary challenge in DFT is the expression of functionals to accurately describe the exchange and correlation energies of electrons. Approximations that have yielded accurate molecular geometries and ground-state energies include the generalized gradient approximation (GGA) method [62]. Pseudopotentials, which serve as approximate, effective potential functions to deal with the core electrons of an atom, that have been successful in the calculations of battery materials have been generated from the so-called projector-augmented-wave (PAW) method [63, 64] as utilized from the software package Vienna Ab initio Simulation Package (VASP) [65].

Survey of Experimental Results and Their Interpretation

The following section will summarize additional examples in recent literature which made use of at least one of the experimental techniques outlined above. Clearly, the body of work available in the field cannot be adequately summarized in a single section. Examples will be grouped by the major components of a Li-ion battery – the electrolyte, SEI, cathode, and anode materials. These particular experiments were selected not only to demonstrate how each technique can provide unique information about the structure of a material but also to emphasize the necessity of utilizing multiple techniques to refine a structural model or determine a chemical reaction pathway.

SEI

XPS has been used extensively to study the composition of the SEI and decomposition products of the electrolyte on electrode surfaces. In the overwhelming majority of cases, the binding energy of the C 1*s*

photoelectron peak position is used to identify various carbon-containing decomposition products. Among the most prevalent species to be identified in the SEI are lithium carbonates – $Li_2\mathbf{C}O_3$, $RO\mathbf{C}O_2Li$, and carbonyl carbons (**C**=O) [66]. There have been a few studies using the O 1*s* and F 1*s* positions to identify LiF [67] and ether linkages [68]. The choice of electrolytes and lithium salts has a profound effect on the decomposition products [69]. Ethylene carbonate electrolytes are rich in $(CH_2OCO_2Li)_2$. XPS has been vital in determining the decomposition rate of electrolytes containing various additives [70] and as a function of temperature [71, 72]. Traces of Li_2O and LiOH were observed in a few instances, but could be the result of side reactions caused by Ar+ sputtering or trace amounts of water [66].

Components of the SEI were also investigated using NMR techniques [73]. ^{7}Li studies, while able to distinguish between lithium atoms in the SEI and those in paramagnetic transition metal compounds using the shift of the resonance, does not provide a lot of information regarding the different types of diamagnetic Li environments. This is because the shift range for Li^+ in salts and other compounds present in the solid electrolyte interphase is small and typically around 0 ppm. Nevertheless, Dupré et al. have used ^{7}Li MAS NMR to characterize interphase layers on electrodes as a function of aging [74–76] mostly using relaxation measurements and line-shape analyses. Leifer et al. have used ^{13}C MAS NMR to characterize electrolyte breakdown products using batteries composed of C-13-enriched carbonates stored at various temperatures [77]. Carbon NMR has a larger chemical shift range, relative to Li, rendering the nucleus more sensitive to changes in bonding or chemical speciation. The carbonates used in the study (a mixture of ethylene carbonate and diethyl carbonate) were selectively enriched in the carbonyl carbon position. By incorporating only one enriched carbonate at a time in the electrolyte mixture, the authors were able to identify the source of specific decompositions products. Strong signals emanating from this carbon site on SEI residing on the anode surface demonstrated that the formation of CO_2 is not a unique breakdown product for the carbonyl groups. The results suggested the formation of a new set of electrolyte breakdown products, including acetals, orthocarbonates, orthoesters, and fluorine-containing alkoxy compounds (from reaction with the breakdown products of the $LiPF_6$ salt used in the electrolyte).

Electrolytes

Carbonate-containing liquid electrolytes are primarily chosen for their ability to dissolve lithium salts and their relatively low viscosity (which facilitates Li-ion diffusion between electrodes). Their flammability has in part led to interest in the use of room-temperature ionic liquids (ILs) as replacements. ILs can potentially operate in a higher voltage window relative to carbonates and also have the added benefit of being more thermally stable and having low vapor pressure. The main drawback of this class of compounds is a high viscosity. Additionally, carbonates may have to be introduced at certain voltages to form a suitable SEI for operation.

Fernicola et al. have synthesized and characterized *N*-butyl-*N*-ethylpiperidinium *N*,*N*-bis (trifluoromethane)sulfonimide (PP_{24}TFSI) IL [78]. A lithium bis(trifluoromethane)sulfonimide (Li-TFSI) salt was dissolved in the ionic liquid and was introduced to a polymer matrix. The dynamics of ^{1}H, ^{19}F, and ^{7}Li, as well as the transport properties of the mobile species in neat PP_{24}TFSI, Li-TFSI mixed with PP_{24}TFSI, and Li-TFSI-PP_{24}TFSI mixed in a polymer membrane were studied using NMR. Spin-lattice relaxation measurements as a function of temperature probed short-range motion on small time scales, while diffusion measurements probed long-range motion on a larger time scale. Comparison of the Arrhenius plots of the ^{1}H spin-lattice relaxation time across the sample series indicates an increase in restrictive motion from the neat ionic liquid to the salt mixture and to the mixture in the membrane. This trend is due to the inherent high viscosity of the ionic liquid and IL-membrane interactions. The T_1 minimums shift toward higher temperatures for the Li-TFSI and membrane samples, reaffirming the dramatic change in the dynamics of the systems. Similar trends were observed for ^{19}F and ^{7}Li across the sample series (the ^{19}F relaxation times were assumed to be above the T_1 minimum). The dynamics of the membrane were well described with single relaxation processes, indicating that all the IL was subject to interactions

with the membrane. Diffusion data were consistent with the previous spin-lattice relaxation measurements. The diffusivity of the PP_{24} and TFSI ions was comparable in all samples. The Li diffusivity in the salt mixture was lower than both the PP_{24} and TFSI ions, owing to a relatively stronger electrostatic interaction between Li^+ and TFSI. However, the TFSI/Li self-diffusion coefficient ratios decreased from 2 to approximately 1, going from the salt mixture to the membrane, resulting in a much higher Li transference number in the matrix. This increase in Li transference number is highly desirable in battery applications.

NMR spectroscopy has also been used extensively to study various electrolytes. Challenges and strategies for successful electrolytes have been previously described in literature [1, 17, 79, 80]. In a few instances, these materials consist of solid polymers [17], which are typically of high molecular weight or cross-linked, gel electrolytes, or composite materials containing additives [81–85]. In recent years, nanoscopic additives have gained recent attention [86–88]. A significant contribution of NMR spectroscopy to the polymer electrolyte community arose from line-width measurements of various resonances as a function of temperature [89–92]. The results showed a correlation between ionic conduction and the degree of mobility of the polymer chains. Moreover, the studies demonstrated that ion conduction predominately occurs in the amorphous phase of the electrolyte at temperatures above the glass transition temperature T_g. The proposition of this "segmental motion-assisted transport mechanism" in the amorphous phase has become broadly accepted among the community.

Lithium transport has also been studied in mechanically [93] or magnetically [94] oriented polymers. An analysis of angular dependent line widths in the static NMR spectra of these materials has shown that the induced reordering of the polymers along the stretching direction affects the ordering of the lithium cations. Additionally, lithium diffusion coefficients were shown to increase along the stretched axis [95]. As mentioned previously, lithium transport generally occurs more readily in amorphous polymer phases. This amorphous transport mechanism, mediated through the motion of the polymer chains, is in sharp contrast to the early model of ion transport in polyethylene oxide which asserted that the cations moved through ordered helical channels throughout the material [96]. The faster diffusion in the oriented samples is not unprecedented however. Gadjourova et al. have shown that for certain compositions of polyethylene electrolyte, the more crystalline phase has a higher conductivity above T_g [97]. Though amorphous phase transport is the dominant transport mechanism in randomly oriented polymer chains, the mechanism of conduction in well-ordered, aligned helices may depend on contributions from many other factors, warranting further basic research and a reexamination of previous models.

Cathode Materials

Olivines and their solid solutions have generated considerable interest as replacement cathode materials [98–100]. In particular, $LiFePO_4$ shows great promise as a low-cost, non-toxic alternative to ubiquitous $LiCoO_2$. Aside from facilitating lithium conduction by "opening up" the framework, substituting a XO_4^{n-} anion for an oxygen allows the redox couple to be tuned using the so-called "inductive effect." [101] Tucker et al. have used ^{7}Li MAS NMR at low field to study the nature of the hyperfine fields in pristine polycrystalline $LiMPO_4$ (M = Fe, Co, Ni, Mn) [102]. The temperature dependence of the inverse magnetic susceptibility was determined for all samples using a SQUID magnetometer. All lithium metal phosphates displayed Curie-Weiss behavior. The susceptibility data was fitted using a linear equation to extract Weiss constants and effective magnetic moments. Temperature-dependent NMR measurements revealed isotropic shifts closely following the Curie-Weiss trend of bulk susceptibility for all compositions, confirming the hyperfine coupling between the ^{7}Li nuclei and the paramagnetic transition metals in these materials. Due to the lowering of symmetry of the MO_6 octahedra from O_h to C_s in these materials [100], the d-orbitals of the transition metals split to two sets – one set of three orbitals at relatively higher energy and another for the remaining two. Assuming a high-spin electron configuration for the materials, the shift contribution for all unpaired electrons in both sets of orbitals was estimated. At 37°C, the unpaired electrons in the orbitals at a higher relative energy contribute approximately −24 to −28 ppm to the total shift.

The unpaired electrons in the set containing the remaining two orbitals contribute 70–79 ppm to the shift. The hyperfine coupling constants for each sample were estimated and showed considerable variation with the type of transition metal. Additionally, the constants were of much smaller magnitude than those measured in lithium manganese oxide spinels [103]. These observations were explained on the basis of the longer *M*–O bonds in Li*M*PO_4 and the polarization of the oxygen electrons to the phosphate structural unit, both of which reduce the degree of covalency of the *M*–O bond. Wilcke et al. have reported variable temperature ^{31}P MAS NMR of the Li*M*PO_4 series along with ^{7}Li MAS NMR data of $LiFe_{1-x}Mn_xPO_4$, where $0 \leq x \leq 1$, using fast sample spinning rates and low static magnetic fields [104]. The ^{31}P shifts were much larger than the corresponding ^{7}Li shifts, demonstrating an increased sensitivity to the P-O-*M* bond covalency which may ultimately be correlated with the degree of Jahn-Teller distortions present in the material, electrochemical performance, and mechanisms that lead to failure.

Leifer et al. [105]. used ^{7}Li MAS NMR to study the structure of lithiated silver vanadium oxide, $Li_xAg_2V_4O_{11}$, where x = 0.72, 2.13, and 5.59. This compound is used in biomedical applications as a primary battery, particularly as the power source for implantable cardiac defibrillators (ICDs). Silver vanadium oxide is a vanadium bronze with semiconducting properties. It has been used successfully as a cathode material in the battery of ICDs due to its high rate capability and its high theoretical capacity (315 mAh/g) to 2 V. Electrochemical and structural studies of the average structure were performed by various authors who concluded that the systems undergoes a multistep reduction mechanism and forms silver metal in the early stage of the overall reaction [106–108].

At least three isotropic resonances were identified, two at approximately −1.5 ppm and −4.4 ppm for all samples studied and a third resonance present at −14 ppm in $Li_{0.72}Ag_2V_4O_{11}$ and $Li_{2.13}Ag_2V_4O_{11}$, which shifts to −54 ppm for $Li_{5.59}Ag_2V_4O_{11}$. Many of the spectral features observed were consistent with previously reported Li spectra of lithiated vanadium oxide materials [109–112]. The three plateaus in the electrochemical profile at 3.2, 2.7, and 2.4 V have been attributed to Ag reduction (3.2 V) and V reduction (2.7 V and 2.4 V) [107, 113]. The inserted Li ions reduce and displace the Ag^+ in the oxygen layers of $Li_xAg_2V_4O_{11}$ [114]. The peak at −1.5 ppm was assigned to Li in the solid electrolyte interphase and lithium salts LiF and Li_2CO_3, with the exception of Li_2O, which would have resonated at 2.8 ppm. The resonance at −4 ppm was assigned to Li in octahedral sites, some of which were occupied by Ag. The lack of shift upon lithiation of this resonance is consistent with the assignment, since the octahedral sites are further away from the vanadium ions and would therefore be least affected by changes in V oxidation state. The peak at −14 ppm was assigned to Li ions in tetrahedral sites near the V atoms as found in $\varepsilon - Li_xV_2O_5$ [115]. The broadening and concomitant shift of this resonance was attributed to the formation of V^{4+} or V^{3+} upon lithiation, whose presence is consistent with previous literature [109, 116, 117]. The profound broadening of the resonance is thus attributed to the paramagnetic vanadium ions [118] and shorter Li-V distances in the material that are a consequence of a collapse in the structure after the displacement of silver during discharge. The lithium shifts that occur at high lithiation levels are also consistent with the reduction of the silver prior to reduction of the vanadium. A line shape analysis of the vanadium spectrum from ^{51}V NMR showed that the crystallinity of the materials decreased steadily as they were lithiated. The $Li_{0.72}Ag_2V_4O_{11}$ had features that were close to the pristine material, implying a simple displacement of the Ag atoms with Li, while preserving the structural integrity and order. The spectral broadening and the loss of definition in the line-shape discontinuities were the most profound in $Li_{2.13}Ag_2V_4O_{11}$ and $Li_{5.59}Ag_2V_4O_{11}$.

XAS and XANES measurements at the Ag K-edge confirmed phase segregation of metallic silver from the SVO structure with an increase in lithium content. The XANES data, normalized to a per atom basis, of silver foil, SVO, and lithiated SVO displayed isosbestic points. This demonstrates that the SVO and Ag are related linearly by stoichiometry. In contrast, the normalized XANES data at the vanadium K-edge of SVO and $Li_{5.59}Ag_2V_4O_{11}$ did not display any isosbestic points, implying no linear stoichiometric relationship between vanadium and lithium between the two samples during lithiation. Shifts in the V pre-edge features of the XANES

spectra of samples were consistent with the change in vanadium oxidation state from +5 to +3. Given the full-width half-maximum of the pre-edge peak in the samples, the authors postulated that vanadium could exist in multiple oxidation states, including V^{4+}.

Yamakawa et al. has recently implemented ^{7}Li MAS NMR to study conversion reactions of binary copper-II compounds (CuO, CuF_2, CuS) [119] and iron fluoride [120]. The results of the binary copper compounds will be summarized first. Prior to this work, two separate mechanisms were proposed for the conversion reaction of CuS by Chung et al. [121]. and Debart et al. [122]. The former reaction mechanism proceeded via a two step process. The first is an insertion reaction to form Li_xCuS, which reacts with Li to produce Li_2S and $Cu_{1.96}S$. The second process involves the subsequent conversion of $Cu_{1.96}S$ to Li_2S and copper metal. Debart et al. proposed that Cu_2S is produced as an intermediate phase, before reacting to produce Cu metal and Li_2S. Possible discharge reaction mechanisms for the CuO system have been proposed by various authors, primarily through the analysis of X-ray diffraction data [123, 124].

Based largely on the Li NMR results of Yamakawa et al., in combination with diffraction and electrochemical analysis, the following reaction mechanisms were proposed for the binary copper compounds. In the CuF_2 system, a simple single-step conversion reaction of the form

$$CuF_2 + 2Li^+ + 2e^- \rightarrow Cu + 2LiF, \tag{22}$$

takes place. In CuO, the following reaction could be written based on the preliminary Li NMR studies:

$$CuO + xLi \rightarrow Li_xCuO \tag{23}$$

The CuS system undergoes more complicated processes. In the first step, the reactions

$$xLi + CuS \rightarrow Li_xCuS \qquad (0 < x \leq 0.16) \tag{24}$$

$$Li_xCuS + (y - x)Li \rightarrow Li_yCuS \qquad (y \sim 1) \tag{25}$$

The second process involves the decomposition of the Li_yCuS phase via

$$(1-z)\left(Li_yCuS + Li^+ + e^- \rightarrow \frac{1+y}{2}Li_2S + Cu\right)(y \sim 1) \tag{26}$$

and the concurrent disproportionation reaction

$$z\left(Li_yCuS \rightarrow 0.5Cu_{1.96}S + 0.02Cu + \frac{y}{2}Li_2S\right) \tag{27}$$

Upon charging, assuming $z \sim 3$ and the Li content extracted from the electrochemical data, the reaction could be written as follows:

$$0.85Li_2S + 0.76Cu + 0.15Cu_{1.96}S \rightarrow Li_y, CuS \rightarrow Li_{0.35}CuS + 1.35Li \tag{28}$$

Electrochemical activity of iron-III fluoride (FeF_3) was first reported by Arai et al. [125]. The compound has theoretical capacity of approximately 200 mAh/g in the 4.5–2.5 V region and 400 mAh/g in the 2.5–1.5 V region. Li et al. [12] and Amatucci and co-workers [13, 14, 126] have since proposed reaction mechanisms for the higher and lower voltage windows:

$$FeF_3 + Li \rightarrow LiFeF_3, \tag{29}$$

for the 4.5–2.5 V region and

$$LiFeF_3 + 2Li \rightarrow Fe + 3LiF, \tag{30}$$

for the 2.5–1.5 V region. In the higher voltage region lithium is inserted into FeF_3 in a two-phase reaction to form $Li_{0.5}FeF_3$ and then through a single-phase reaction to form $LiFeF_3$. Badway et al. have proposed that during the conversion reaction the iron metal and lithium fluoride react to form a, "rutile-like FeF_2" structure [14]. Doe et al. have performed first-principles calculations suggesting that intermediate phases could form during the electrochemical process [127].

The ^{7}Li MAS NMR spectra of lithiated FeF_3 samples, taken at cutoff voltages between 3.3 and 1.7 V, display two resonances at approximately 0 ppm and another between 104 and 172 ppm. The resonance at higher frequencies is relatively broader than the peak at 0 ppm. The larger shifts were attributed primarily to the Fermi contact interaction between the Li nuclear spins and the unpaired Fe electrons, which occur via the Li-F-$Fe^{3+/2+}$ bonds. The larger line width of these peaks is attributed to the through-bond and through-space interactions between the ^{7}Li nuclei and rapidly fluctuating electronic dipole moments of the iron, which efficiently relaxes the nuclei and consequently reduces T_1 and T_2. Previous ^{6,7}Li NMR spectroscopy

performed by Grey and co-workers on lithium iron oxides showed that typical shifts for lithium were between 280 and 520 ppm [128, 129]. The smaller shifts observed in the iron fluoride systems was attributed to the presence of Fe^{3+} and Fe^{2+} coordinated to Li and the decreased covalency of the Fe-F bond relative to the Fe-O bond.

The samples arrested at 3.3 and 3.0 V both display a peak at 172 ppm, whose intensity increases with lithium content. The constant shift is indicative of an average Fe oxidation state around the Li coordination environment that remains unchanged. These results are consistent with the proposed two-phase region involving a Li_yFeF_3 ($y \sim 0.5$) phase and an unlithiated FeF_3 phase. The peak at 172 ppm gradually shifts to lower frequency between Li = 0.5 and 0.75, corresponding to voltages of 3.0 and 2.5 V respectively. This observation is in agreement with a solid solution reaction in which Li is inserted to the $Li_{0.5}FeF_3$ phase and a reduction from Fe^{3+} to Fe^{2+} occurs. The resonance does not increase in intensity but noticeably broadens into the baseline at Li = 1.0 (1.7 V), which is ascribed to very fast nuclear relaxation due to the presence of high-spin Fe^{2+} ions.

The ^{7}Li MAS NMR spectra of samples with Li = 1.0–3.0 display a single resonance at 0 ppm with spinning sidebands spanning over 5,000 ppm. Upon discharge, the width of the signal manifold increases as does the broadening of each individual peak. These observations are consistent with the formation of iron nanoparticles. Due to the relative ease of the measurement, it was rationalized that the nano-sized iron metal was not ferromagnetic but superparamagnetic. Liao et al. have shown that particles less than or equal to 6.6 nm display superparamagnetic properties [130].

^{6}Li MAS NMR was performed on the same sample set and revealed a second resonance for the Li = 1.7 sample, at approximately 86 ppm. This peak was assigned to Li in an insertion phase with a higher Fe^{2+}/Fe^{3+} ratio. An additional resonance at 104 ppm was observed in the ^{6}Li spectrum of the Li = 1.0 sample. The relative intensity of the 86 ppm peak was smaller than the 104 ppm peak of the other samples presumably due to the onset of the conversion reaction. Upon charging, the ^{6}Li MAS NMR spectra of Li = 0.5–3.0 revealed resonances in similar positions as the discharged samples, i.e., peaks at 0 ppm and between 80 and 168 ppm, with a gradual shift from 80 to 168 ppm for the Li = 2.0–0.5 samples. The similarity in the peak positions of the charged and discharged samples imply that the Li ions return to very similar local environments and that Fe^{2+} and Fe^{3+} are both present at the end of the charge, having an average iron valence state of $Fe^{2.5+}$. Moreover, the total width of the sideband manifold for the 0 ppm resonance decreases, suggesting that the concentration of superparamagnetic Fe decreases upon charging.

A study by Bréger et al. on $LiNi_{0.5}Mn_{0.5}O_2$, employing X-ray and neutron PDF analysis in conjunction with Li NMR serves as an ideal illustration of employing complementary techniques to obtain clear structural constraints and generate a detailed model of the material [131]. In order to determine the local environment of each transition metal independently, three samples were prepared for neutron diffraction measurements: $^6LiNi_{0.5}Mn_{0.5}O_2$, $^7LiNi_{0.5}Mn_{0.5}O_2$ and $^7Li^{ZERO}Ni_{0.5}Mn_{0.5}O_2$, corresponding to a Li-6-enriched, Li-7-enriched, and a Li-7-enriched sample containing appropriate amounts of ^{62}Ni to natural abundance nickel in order to produce null scattering from the element, referred to as $^7Li^{ZERO}$. The PDF data revealed distributions in the metal-oxygen bond lengths arising from local distortions which were not captured from the average $LiCoO_2$ structure. The PDF data also took into account the superstructure reflections, arising from the non-random distribution of transition metals in the layers, in the scattering data that could not be indexed (labeled) using the $LiCoO_2$ structural model in Rietveld refinements. NMR results and RMC calculations provided further evidence that the cations were non-randomly distributed in the transition metal layers (see Fig. 8). On average, Ni atoms are surrounded by more Mn atoms in the first cation coordination shell (nearest transition metal neighbors) and by Li and Ni atoms in the second coordination shell (next nearest transition metal neighbors). Manganese atoms tend to be surrounded by Li and Ni in the first coordination shell and by other Mn atoms in the second coordination shell. The raw data can be compared to different transition metal–ordering schemes proposed from first-principles calculations, transmission electron microscopy, and previous NMR results [132–135]. The two-ordering schemes proposed were the so-called honeycomb and flower arrangements.

Lithium Ion Batteries, Electrochemical Reactions in.
Figure 8
Neutron PDF data of $^{7}LiNi_{0.5}Mn_{0.5}O_2$ that was fitted (**a**) using an ideal $LiCoO_2$ structural model where the Ni, Mn, and Li atoms are randomly distributed in the transition metal layers and (**b**) after a series of Reverse Monte Carlo (RMC) calculations which accounted for cation ordering. The raw data is shown in *black*, the fit in *red*, and the difference between the two in *blue* (From [131])

Lithium Ion Batteries, Electrochemical Reactions in.
Figure 9
Variable temperature ^{7}Li MAS NMR spectra of $Li_3V_2(PO_4)_3$ displaying the temperature dependence of the shift and the coalescence of the various lithium environments due to exchange, from [136]. The resonance around 0 ppm is due to a diamagnetic impurity

While the numbers of metal-metal contacts extracted from the experimental data show that a completely random distribution of the transition metals is a poor structural model, it was difficult to distinguish between the flower and honeycomb ordering schemes.

Cahill et al. have used variable temperature ^{7}Li MAS NMR spectroscopy to study the lithium dynamics of monoclinic $Li_3V_2(PO_4)_3$ [136]. The three lithium sites at 103, 52, and 17 ppm (labeled Li3, Li2, and Li1 respectively) are clearly resolved and unambiguously assigned at a sample spinning speed of 25 kHz and a magnetic field strength of 7 T. The relative intensity of the peaks, including contributions from the respective side-band intensities was 1:1:1, as predicted from the crystal structure. One-dimensional ^{7}Li MAS NMR spectra taken from 276 to 364 K (see Fig. 9) display a linear shift dependence with respect to temperature indicative of Curie-Weiss behavior. The electronic insulating nature of the materials as well as the aforementioned Curie-Weiss behavior as a function of temperature confirmed that the origin of the lithium shifts is due to hyperfine interactions. Additionally, the resonances begin to coalesce as the temperature is increased. This implies the hopping of Li atoms between different sites in the crystal lattice. According to the data, Li1 and Li2 begin exchanging first at relatively lower

temperatures. Based on the separation of the peaks before coalescence at 316 K, an estimation of approximately 6.5 kHz (corresponding to a correlation time τ_c of 154 μs) was determined as the lithium hopping rate between the two crystallographic sites. By 364 K, all three Li resonances have coalesced, implying that all lithium atoms are exchanging between the three sites.

Through an analysis of 2D Exchange spectra of the sample as a function of temperature, the authors were able to extract activation energies for lithium conduction between Li1-Li2, Li2-Li3, and Li1-Li3 sites. The activation energies extracted from the NMR measurements can be correlated with structural factors which could affect Li-ion mobility, such as the internuclear distance between the Li sites and bottlenecks in the conduction pathway. The activation energy of the hopping between two Li sites increased when the internuclear distance between Li sites increased and when the distance of the shortest Li-O contact decreased. The lithium ions in $Li_3V_2(PO_4)_3$ can be visualized as existing on sheets along the crystallographic ac plane. The implication of these NMR results is that conduction primarily occurs in one dimension, in a straight line across different Li sites using a series of oxygen atoms along the channel to facilitate the transport. These quantitative measurements are invaluable for rationalizing conduction mechanisms in these materials and understanding transport properties along at small length scales.

Anode Materials

Lithiated graphite has been one of the most widely investigated anode materials [137–139]. The first reported study of lithium intercalated into graphite was by Conard and Estrade [140]. The insertion results in changes in the electronic properties which can be monitored by the Knight shift of the intercalated ^{7}Li using NMR techniques. Increasing the performance of graphitic anodes in Li-ion batteries has been a long-standing research initiative. Partially oxidized or pyrolytic graphite, along with hard carbon, have been investigated to improve performance [141–145]. The chemical and structural modification offered some degree of control over the reversible and irreversible capacity changes in the cell or improving the cycling degradation by facilitating SEI formation.

Most Li NMR studies are performed ex-situ, whereby a material has been investigated at discrete points in the charge-discharge profile. This requires multiple batteries to be made and cycled at those specific points, before being sacrificed for the NMR study. Studies employing such a protocol are time-consuming and can be complicated by sample variability. Moreover, the products of short-lived processes cannot be easily identified or quantified. Recently, Li NMR spectroscopy has been applied in-situ under routine operating conditions. To date, these *in-situ* experiments have been under static conditions, i.e., no magic angle spinning. The first *in-situ* NMR experiment was performed by Gerald et al. [146]. An NMR toroid was used for both spectroscopy and imaging. These initial experiments struggled from poor signal-to-noise ratios, in part due to the incompatibility of a standard lithium ion battery with the toroidal design. Chevallier et al. and Letellier et al. circumvented some of the initial issues by implementing a so-called, "plastic lithium-ion battery" [147, 148] which introduced a flexibility to the battery and eliminated the need for external pressure to maintain contact between the various components of the cell. These initial *in-situ* studies were performed on modified carbonaceous materials designed to replace graphitic carbon as the anode.

Another replacement of graphitic carbon in lithium ion batteries is silicon, due to its large volumetric and gravimetric energy density – 8,322 mAh cm^{-3} (calculated from the original volume of Si) and 3,572 mAh g^{-1} respectively. The high capacitance induces large volumetric changes in the electrode (~300%) which results in issues of capacitance retention, particle fracture and battery design [149]. The Li-Si binary phase diagram contains four reported crystalline lithium silicides – $Li_{12}Si_7$, Li_7Si_3, $Li_{13}Si_4$, and $Li_{21}Si_5$ [150]. These complex materials lie on the border between intermetallic compounds and Zintl phases and contain orbitals delocalized over many lithium ions. Key et al. [149]. have collected ^{7}Li of these model compounds in order to correlate shifts with local environments in silicon based electrodes. The spectrum of $Li_{21}Si_5$ has very broad resonances at approximately 60–100 ppm, owing to the Knight shift. In contrast to $Li_{21}Si_5$, the other lithium silicide phases have single, broad resonances between 6 and 19 ppm, indicative of vastly different electronic properties of each compound.

The authors hypothesized that the various lithium sites in the model compounds were not well-resolved due to a possible combination of factors – slow Li motion, residual ^{7}Li-^{7}Li dipolar coupling, and structural disorder. Nevertheless, a trend toward smaller shifts, implying a greater electron density around the Li atom and more shielded environments, is observed as the Li/Si ratio increases. The resonances with larger shifts in the semi-conductors were found in compounds with Si-Si bonds, whereas smaller shifts were observed in the samples with isolated Si atoms.

The same system was investigated by in-situ ^{7}Li NMR using a plastic battery to monitor real-time changes during a complete charge and discharge at a C/75 rate. The data set largely agrees with the ex situ measurements with slight variations in the shifts of the peaks which were ascribed to the relatively poor resolution of static NMR and small susceptibility effects from metal components in the battery. One striking difference between the in situ and ex situ data was the presence of a new resonance at approximately −10 ppm, at the bottom of the discharge profile (<30 mV), where diffraction measurements displayed evidence for crystalline $Li_{15}Si_4$. The intensity of the −10 ppm resonance decreased rapidly upon charging. A second battery that was fully discharged ex-situ was then monitored using *in-situ* ^{7}Li NMR. The −10 ppm resonance disappeared as the battery relaxed over a period of approximately 10 h. The phenomenon was attributed to a reaction between the metastable $Li_{15}Si_4$ phase with the electrolyte through a "self-charge" mechanism. The reactivity of the amorphous lithium silicides and the self-discharge mechanism may lead to capacity loss or safety concerns. However, the authors noted that the use of carboxymethylcellulose (CMC) as a binder inhibited the discharge process significantly, implicating the reduction of side reactions with the electrolyte and, hence, capacity losses.

Future Directions

In order to meet the ever-increasing demand for energy and portable electronic devices, innovation in the battery community must be a priority. A prerequisite for innovation is a fundamental understanding of chemical reaction pathways and structure determination on a broad length scale. As a natural response to this challenge, there has been a surge of multidisciplinary collaboration. These efforts have been exceedingly successful in elucidating the atomistic details of a plethora of materials and providing a clear direction for future investigations. Breakthroughs are contingent upon a continued and open dialogue between scientists spanning a wide array of expertise. Electrochemical behavior is inextricably related to structure. Consequently, there will be an increasing need to accurately probe and quantify changes in chemical speciation, bond angles, bond lengths, and oxidation state. A particular challenge is to model disordered and nano-sized materials. Implementation and advancement of techniques sensitive to the local environment will be of utmost importance to place structural constraints in these classes of compounds. Such constraints will be invaluable to the computation community in their efforts to predict the phases and electrochemical properties of new materials. Investigation of various room-temperature ionic liquids, for replacement of commonly used carbonate electrolytes, as well as a long-term investment into novel material design and characterization will dominate the battery research community for many years to come. It is only through a concerted effort among materials engineers, analytical, and computational scientists that we are able address the issues of today and those of tomorrow.

Acknowledgments

The authors thank past and present members of the solid-state NMR group at Hunter College for their contributions and gratefully acknowledge support from the US Department of Energy and the U.S. Office of Naval Research.

Glossary

Abuse External stress applied to a battery or cell that is not anticipated to occur under normal operating conditions and may cause the cell to experience thermal runaway.

Cascading Process by which one cell in a battery releases sufficient heat that thermal runaway of one or more neighboring cells in a pack ensues.

Field-failure *Infrequent* safety incident that occurs in lithium-ion cells/batteries in the field under "normal" operating conditions and does not appear to have an obvious external trigger, but is often caused by an internal short circuit. Such internal short circuits are often caused by foreign metal particles.

Safe Zone For a given cell construction and materials, and for a given heat transfer environment, conditions of energy and power associated with an internal short such that a thermal runaway is not possible.

Thermal runaway A process of uncontrolled heat release and rapid temperature rise.

Threshold energy For a given cell design and heat transfer environment, an energy value dissipated in an internal short below which no thermal runaway is possible.

Threshold power For a given cell design and heat transfer environment, an internal short power below which no thermal runaway is possible.

Trigger for thermal runaway A stimulus that initiates thermal runaway in a Li-ion cell. Examples of potential triggers include a variety of abuses as well as internal short circuits created by foreign metal particles.

Definition of the Subject and Its Importance

Safety of lithium-ion batteries is a critical topic that has not received adequate attention in the past, largely due to the fact that data regarding safety failures have been severely restricted. As a result, there are numerous misunderstandings in a field that has not received the same degree of scientific and technical rigor as other areas of lithium-ion battery technology development. However, safety of lithium-ion batteries will become even more important as lithium-ion technology enters transportation markets. Under suitable triggers, Li-ion cells can experience thermal runaway, i.e., the rapid increase in cell temperature accompanied by venting, vent-with-flame, ejection of cell parts, fire, and explosion. Safety failures of lithium-ion cells can result from a variety of triggers including overcharging, overheating, crushing, mechanical impact, and external short circuits. Safety tests have been devised for all these abuses, with varying degrees of fidelity. However, most safety incidents that have taken place with lithium-ion batteries occur due to the slow and rare development in cells of internal short circuits that mature to the point that they result in thermal runaway. Most safety tests carried out in the laboratory or factory do not replicate the conditions by which safety incidents actually occur in the field. These issues are characterized in detail, and an improved overall framework for considering lithium-ion battery safety is suggested.

Introduction

Since their introduction in 1991, lithium-ion batteries have become the dominant rechargeable battery technology for portable products and are beginning to make inroads in transportation and stationary storage applications. Lithium-ion battery technology provides the highest available energy density of any long-cycling rechargeable battery, which has been the most significant factor leading to its widespread adoption. As of this writing, over 4.5 billion lithium-ion cells (almost 40,000 MWh) [1] will be expected to be produced in 2011, the bulk of which are used in consumer electronics applications such as laptop computers and cell phones. While the demand for such cells is increasing at the rate of 15% on a year-on-year basis, emerging applications can significantly increase the Li-ion market. It is anticipated that emerging transportation and stationary storage markets will lead to dramatic increases in the volume of Li-ion production. One recent estimate places automotive Li-ion demand in 2020 at 150,400 MWh, in contrast to 72,500 MWh projected for portable applications in that year. The transportation and stationary applications are expected to use larger capacity cells than those employed for consumer electronics applications [1].

Despite the obvious success of Li-ion technology, safety concerns remain [2]. Under suitable triggers, Li-ion cells can undergo venting, vent-with-flame, ejection of cell parts, fire, and explosion as the consequence

of a process of uncontrolled heat release, termed "thermal runaway." This risk is not surprising given the possible sources of heat release within a cell. Essentially, Li-ion batteries store a very large amount of electrochemical energy, which can be released as heat, for example, through an internal short. The electrochemical energy content of state-of-the-art Li-ion cells is by itself sufficient to raise cell temperature to 700°C if completely dissipated within the cell under adiabatic conditions. But furthermore, Li-ion cells contain energetic materials that can undergo exothermic decomposition reactions within the cell, as well as containing combustible organic solvents (with heat of combustion that is about a third of the heat of combustion of gasoline) and combustible carbonaceous anode materials, both of which can burn in atmospheric oxygen if exposed under suitable ignition conditions. The heat release from such reactions can be as much as ten times the stored electrochemical energy.

Safety failures of lithium-ion cells can result from a variety of triggers. Overcharging, overheating, crushing, mechanical impact, and external short circuit all represent forms of external triggers (often termed "abuse" conditions) that can lead to safety incidents. These external abuses have been extensively studied. Battery engineers have developed several cell-level and pack-level tests to evaluate how a cell/battery responds to the abuse, and they have also developed technologies and approaches to manage the cell and battery response to such external abuses [3–11]. Standardized tests also have been developed to assess cell and battery "tolerance" to external abuses [12, 13]. In general, this chapter shall try to draw distinctions between tests used to screen cells/batteries for their tolerance to a given trigger and the actual tolerance of a cell/battery to the given trigger (i.e., the effectiveness of the test).

Safety concerns have been heightened by highly publicized safety incidents and ensuing widespread recalls of lithium-ion batteries used in laptop computers and cell phones [14, 15]. When these rare safety incidents occur, lithium-ion batteries operating under otherwise normal conditions undergo what appear to be spontaneous thermal runaway events, often with violent flaming and extremely high temperatures. Moreover, these failures usually involve cells and cell designs that have passed extensive abuse testing, including the standardized abuse safety tests. *Most such Li-ion safety incidents in the field are not preceded by any obvious external abuse*. We refer to these spontaneous safety incidents as "field-failures". The fact that cells involved in field-failures generally have passed all standardized safety tests is the first clue that these incidents should be given special consideration. Internal shorts – not external abuses – cause field-failures far more frequently than is generally appreciated. Such shorts are a major focus of this chapter.

Given the near ubiquitous use of Li-ion batteries, field-failures may result in significant property damage and may also prove dangerous to users, not to mention the enormous costs of the recalls they have prompted. Furthermore, the advent of new transportation and stationary applications employing cells larger than those used in portable applications, and often with many cells in series, raises the threat of even more severe outcomes.

Although field-failures and the ensuing recalls have resulted in significant financial losses for the battery industry, relatively little is known or published about them, or the underlying causes of such incidents. Outside of the battery companies and their customers, very few organizations have had an opportunity to carry out careful postmortems of cells and batteries involved in these incidents. As a result, a very large fraction of the lithium-ion battery community, including materials companies, national laboratories, and the worldwide academic community, are not able to approach the lithium-ion battery safety issue with the same scientific and technical rigor that they apply to other aspects of lithium-ion technology. We believe that if better background information were made available to engineers and scientists across the battery community, there would be a profound impact on widely held perspectives regarding safety, how to test for safety, and what actually makes a lithium-ion cell/battery safe. Importantly, most safety tests carried out in the laboratory or factory do not replicate the conditions by which safety incidents actually occur in the field. We will describe this conundrum in greater detail below.

We (at TIAX) are one of the few organizations that have had an opportunity to carry out a significant number of detailed investigations of actual lithium-ion safety incidents [16–21]. Although confidentiality requirements preclude us from showing specific

examples of field-failure cell postmortems, we will describe general observations and conclusions in this chapter. We are hopeful that the lessons learned from such work can enhance the overall perspective of the lithium-ion battery community and support some of the insights developed in this chapter. Finally, an improved overall framework for considering lithium-ion battery safety is suggested.

Basis for Li-Ion Safety Concerns

Li-ion cells are widely understood to have higher energy content than other rechargeable batteries, but this perception is generally focused only on their higher *electrochemical* energy density. While that perception is correct, the heat release associated with the exothermic reactions of all of a cell's contents must also be considered when evaluating safety. In the case of Li-ion technology, this heat release can exceed ten times the stored electrochemical energy content if in the field-failure process, all the cell's combustible contents are reacted with air. For example, Table 1 summarizes the typical contributions to the heat release in a generic Li-ion cell. The table lists the key chemical reactions and provides estimates of the following:

- Temperature range over which the rates of these reactions are significant
- Total heat release from these exothermic reactions
- Heat release that can be attributed to the particular reaction in a 10-Wh 18650 cell (electrochemical energy of 36 kJ)

As can be seen from the table, the anode and cathode reactions with electrolyte and the self-reaction of electrolyte contribute significantly to the heat release relative to the electrochemical energy content of the cell. The mechanism and kinetics of these reactions have been studied extensively in the literature [22–29]. However, complete combustion of the solvent results in much higher heat release. Note that even in Li-ion cells with metal oxide cathodes there is insufficient oxygen available within the cell to completely combust the solvent, a factor not always recognized by many safety investigators. Thus, a major fraction of the solvent combustion can only occur outside the cell. An even greater release of heat occurs if the graphitic anode content of the cell is combusted upon exposure to atmosphere; postmortem audits show that this does in fact occur in many field-failures. Graphite's heat of

Lithium-Ion Batteries, Safety. Table 1 Summary of contributions to heat release in a lithium-ion cell

Process	Temperature range (°C)	Energy release	Energy relaese in a 10 Wh 18650 cell
Anode decomposition and reaction with electrolyte	80–120	~400 J/g-anode[a, b]	~11 KJ
	150–300	~1,300 J/g-anode[a, b]	
Cathode decomposition and reaction with electrolyte	150–300	~1,600 J/g-cathode[a]	~23 KJ
Self-reaction of salt with solvent	250–400	~900 J/g electrolyte[c]	~4 KJ
Complete combustion of solvent[d]	Auto-ignition temperature ~450	~18 KJ/g Solvent	~110 KJ

[a]Values estimated from DSC and ARC measurements of cell components at TIAX, for charged active (graphite and $LiCoO_2$) in contact with standard carbonate electrolyte ($LiPF_6$ in carbonate solvents)

[b]There are two parts to the anode decomposition reactions, a low temperature part typically attributed to the decomposition of SEI film, and a higher temperature reaction involving the reaction of the anode with the electrolyte

[c]Values estimated from DSC and ARC measurements of standard Li-ion electrolyte

[d]There is insufficient oxygen available inside a typical 18650 cell, even with a metal oxide cathode, to effect complete combustion of the solvent that would be present in the cell. However, if vented at high temperatures or vented in the presence of an ignition source, the solvent can burn outside the cell

Lithium-Ion Batteries, Safety. Figure 1
Estimate of the adiabatic temperature rise from heat release in a 10-Wh Li-ion 18650 cell

combustion is nearly 33 kJ/g, meaning that complete combustion of a 2.6-Ah cell's graphite content will generate about 260 kJ.

Adding graphite's combustion heat to the energies listed in Table 1, the total energy release by an 18650 cell can exceed 400 kJ. The heat that can potentially be released within the cell absent of atmospheric combustion, shown in Table 1, can itself be significant and can drive severe cell temperature increases. The highest temperatures to which cells might be driven by these processes can be estimated by considering the adiabatic temperature rise associated with the different sources of energy release discussed above, as summarized in Fig. 1. Release of electrochemical energy alone, as by full discharge of the cell through an internal short, can raise the cell temperature by more than 700°C under adiabatic conditions. Furthermore, the anode and cathode exothermal reactions together can also raise the cell temperature by 700°C. These temperatures are significantly higher than the autoignition temperature of the solvent, and hence, if the solvent is ejected from the cell at these temperatures, it is likely to combust outside the cell, further stimulating the development of very high temperatures, and igniting the graphitic anode with explosive combustion.

Table 1 and Fig. 1 illustrate the powerful energetics underlying thermal runaway events. An increase in temperature can stimulate significant heat release from the exothermic anode, cathode, and electrolyte decomposition reactions. If the rate of heat removal is slower than the rate of heat generation, thermal runaway will eventually occur, accompanied by enormous heat release and very high temperatures.

Triggers for Li-Ion Thermal Runaway

In general, some form of trigger, or initiating process, is required to produce a thermal runaway event. The previous section amply illustrates that triggers producing increased temperature of either the whole cell or a significant region of the cell can result in thermal runaway. Table 2 summarizes some common triggers. Ideally, battery developers and implementers can utilize safety tests that specifically screen for a cell's or battery's tolerance to a given trigger.

The triggers that have received the greatest attention include abuse conditions such as external heating, overcharging, external shorting, impact, penetration, etc. Some of these triggers are relatively easy to anticipate as risks, and to study and to develop screening

Lithium-Ion Batteries, Safety. Table 2 Summary of triggers that can lead to thermal runaway of Li-ion batteries

Trigger	Why can this occur?	Is this managed?
Overcharge	Defective connections, failure of charging circuit	Yes, battery management system Yes, cell-level safety devices
Overheating from external sources	Battery back placed too close to a heat source	Yes, cell-level safety devices open the cell at suitable internal pressure
Cell crushing creating massive internal shorts	Physical abuse of battery pack	Yes, design enclosures are built more tolerant to specific abuses
Internal short-circuits (a.k.a., field failures)	Internal-short caused by manufacturing defects	No, new technologies needed
Cascading of thermal energy release	Affected cell can raise the temperature of surrounding cells	No, new technologies needed

tests for, often by selecting a set of abuse conditions that are reasonably plausible. In fact, numerous standardized (or semi-standardized) abuse tests have been developed to assess abuse tolerance (a broader all-encompassing term might be "trigger tolerance"). Examples of such tests include the hot box test, the forced overcharge test, the external short circuit test, etc. [12, 13] These tests are not reviewed in detail, except to point out that they do not generally replicate the conditions in which actual safety events occur in the field. Certain other triggers present more difficult challenges with respect to development of truly effective safety screening tests. In addition, some safety tests can be "gamed," i.e., manipulated to favorably alter the outcome by carrying out the tests under certain conditions, or by modifying cells so that they can pass the tests rather than demonstrate true tolerance to the particular abuse. Situations where definition of plausible screening safety tests may *not* be possible are highlighted. Table 2 identifies (rows 4 and 5) two such triggers.

Technologies and components such as PTCs, CIDs, vents, and safety circuits have been incorporated in today's lithium-ion cells and packs in order to manage safety with respect to many external abuse triggers.

The internal short is yet another trigger that can lead to thermal runaway. Essentially, cell discharge through the internal short causes i^2R heating and high temperatures in the vicinity of the short. High temperatures in the vicinity of the short circuit can stimulate additional heat release from the exothermic decomposition reactions described above, which can then result in thermal runaway. Thermal runaway following internal shorting is discussed in greater detail in a subsequent section describing simulation tools and results. Evidence from investigations of field-failures suggests that they are predominantly triggered by internal short circuits that are very clearly not present or detectable in fresh cells.

Tests (e.g., see Refs. [30–36]) are being developed to simulate an internal short circuit by deliberately placing particles in cells or by controlled pinch tests. There are also some advocates for the use of the nail penetration test or the round bar crush test as means of screening cells for tolerance to internal shorts. However, these tests are not standardized at the moment, and it can be argued that there are fundamental challenges in mimicking the behavior of an internal short circuit that develops only during normal charge/discharge cycling in the field. Later sections will discuss in greater detail the testing issues with respect to internal shorts, and reasons are suggested as to why cells cannot be screened for safety with respect to this trigger. Furthermore, currently there are no strategies to manage internal short-related thermal runaway of Li-ion cells. We will suggest some strategies later in this chapter.

Thermal runaway of a single cell in a lithium-ion pack will frequently stimulate a "cascading" event. In this phenomenon, some time after one of the cells in a pack undergoes thermal runaway consequent to an external or internal trigger, other cells in the battery pack also go into thermal runaway, sometimes as

a series of discrete events. The enormous amount of heat release from a cell undergoing thermal runaway can cause the temperature of one or more nearby cells to rise to the point that they too are stimulated to thermal runaway. Although cascading has been recognized as a risk for Li-ion batteries, adequate cascading screening safety tests have not been developed, and anticascading technologies are not routinely incorporated into battery packs.

The remainder of this manuscript focuses on the internal short and its critical role in triggering thermal runaway. The review of key observations summarized from our audits of field-failure incidents leads to the deduction that the majority of such safety events are due to internal short circuits caused by foreign metal particles in lithium-ion cells, and accordingly, most of this chapter focuses on them. This summary is followed by discussions of the likely mechanism of internal short formation as probed by experimental measurements. Then, simulations are described that elucidate the factors controlling thermal runaway following an internal short circuit, and that provide the basis for a novel construct allowing the first "quantification" of Li-ion battery safety associated with any given cell and its operating environment. The key differences between abuse tolerance and field-failures are then described, followed by discussion of an overall framework to improve the safety of Li-ion batteries.

Key Observations from Analysis of Field-Failures

This section summarizes key observations from our direct investigations of lithium-ion battery field-failures, including work carried out with some of the largest battery and portable device manufacturers in the world. While confidentiality restrictions prevent us from incorporating specific details of these safety incidents, we are able to highlight major observations and insights gained from this work, and from other sources. We have learned that:

- Field-failures occur at a frequency of one failure in 5–10 million cells for the most accomplished manufacturers. Such failures are overwhelmingly attributable to internal short circuits occurring during otherwise "normal" operation, with no outward signs of impending failure.
- These internal shorts are not discernible at the point of manufacture but appear to develop over time. Typically, the failure occurs only after a significant service time in the field (e.g., more than 3 months) and may not occur for 1–3 years. Thus, "fresh" cells do not necessarily exhibit the conditions that lead to a safety event.
- A high proportion of these internal short circuits are caused by extraneous (foreign) metal particles introduced into the cell during the manufacturing process. Evidence for such particles can be found in cell postmortems, except that a high level of destruction often hinders or prevents satisfactory investigation. While metal particles may enter the cell-making activity with incoming materials, they also can be produced by a wide variety of the material processing and metal cutting and shaping operations used in cell manufacturing. The exact composition of the metal causing a given field-failure is often not known with certainty, but iron, nickel, and zinc have all been known to cause field-failures; in typical $LiCoO_2$/graphite cylindrical cells, these elements are not normally present in the jelly roll, and thus have been implicated from postmortem analysis of cells.
- Various processes are employed by battery manufacturers to reduce the frequency of metal particle generation and/or incorporation in cells. These processes include extensive shrouding of key operations, strategic placement of magnets, use of higher grade metals in various operations, and aggressive monitoring of replacement schedules for all cutting and forming tools. Additional measures, such as high-pot and formation aging tests, are employed to catch and reject cells exhibiting internal shorts during cell production and qualification [37, 38].
- A surprisingly high percentage of lithium-ion cells have foreign metal particles in them. Given the rarity of field-failures, it is clear that not all particles in the cells lead to internal shorts or to thermal runaway. In fact, it is likely that the vast majority of internal short circuit defects occurring after some time in the field are manifested as a "dead" cell/pack, rather than as a violent field-failure.
- In field-failures, an induction period lasting on the order of minutes is often reported, during which

self-heating of the battery is discernible by users/observers, prior to violent flaming and explosion.

- Postmortem examinations of actual field-failures indicate that all or portions of a cell have experienced very high temperatures. For example, cells from incidents routinely exhibit multiple localized silver-colored metallic beads. These beads are recondensed aluminum, which melts at 660°C. In some instances, there are areas in which copper current collectors have also experienced melting. Copper melts at 1,085°C.
- Neither the actual mechanism of short circuit initiation nor the mechanism by which an internal short leads to a thermal runaway is fully understood yet. After the fact, postmortems show a level of destruction that renders it impossible to ascertain the exact morphology that existed at the point of thermal runaway. We use experimental and simulation results to discuss the likely mechanism of short formation, and the factors that control thermal runaway following an internal short.

Implications for Managing Field-Failures

Most safety incidents that have been observed and evaluated involved portable computer battery packs. Although some incidents have taken place in mobile phone batteries, computers use many more cells, with cells in series and in parallel. Our discussion of the mechanism of short initiation will show that such failures are also possible in HEV, PHEV, and BEV cells. Without suitable safety technologies in place, safety incidents in HEV, PHEV, and BEV packs are likely to be more severe than those observed in laptops owing to the larger cell sizes employed (approximately 2–30 times on an energy basis) and the lower impedance of the cells. Furthermore, with roughly 75–80 cells per pack (for cells in a single string) and the total energy per pack approximately 20–200 times larger than that of computer packs, the consequences of thermal event "cascading" is a major concern. Field-failure in a vehicle pack could inflict far greater damage than that caused by notebook computer batteries.

Because the consequences of these rare safety events can be so serious, especially with increased use of lithium-ion in transportation applications, it is necessary to recognize that no manufacturing environment can always operate with zero defects. Therefore, given the recognition that foreign particles in cells can never be completely eliminated, there is a need to develop safety technologies that are "on guard" to catch their deleterious effects as early as possible. A useful perspective is to recognize that achieving Li-ion systems which are totally free from the threat of spontaneous safety events is *not* a quality problem. For example, the rate of field-failures for cells produced by the most experienced manufacturers is already at a very low level – one failure in 5–10 million cells produced, which already far exceeds six sigma manufacturing quality guidelines. These manufacturers typically benefit from the most powerful elements of a learning curve – they have produced large numbers of cells (over a billion in several cases) over a very long period of time (more than a decade). It is reasonable to assume that less-experienced manufacturers will eventually approach similar levels, but no manufacturer will achieve zero defects in perpetuity.

Manufacturing improvements should, of course, continue to be implemented whenever possible, but it should be recognized that improvements in the cleanliness or quality control of manufacturing lines are not the fail-safe solution. Manufacturing "quality" is already maintained at a very high level. The defect rate is already very low and not readily correlated with the level of small extraneous metal particles in cells. Greatly reducing the level of particles in cells could probably only be accomplished with significant (and unacceptable) additional processing costs. (For example, consider the manufacturing quality levels that must be achieved in the semiconductor industry, and the associated costs.) Clearly, a new approach is needed to make significant progress toward improving the safety of Li-ion batteries and, in particular, to deal with the insidious role of the internal short circuit in causing lithium-ion safety events.

We have been developing tools and techniques to enable the development of new technologies to manage field-failures. In the following sections, some insights are described that have been gained from exercising these tools; namely, the likely mechanism by which a foreign metal particle forms an internal short, and the mechanism by which an internal short then stimulates thermal runaway.

Likely Mechanism of Internal Short Formation in a Field-Failure

The exact mechanism of field-failure due to foreign metal particles in cells may never be known with certainty, given the rarity of events and the extensive destruction that takes place in affected cells. The realization that field-failures are rare has a number of practical consequences for studies of internal short formation, for attempts to identify electrical signals warning of developing internal shorts, and for development of any safety technology. In particular, a reliable method(s) to generate internal shorts "similar" to those that lead to thermal runaways in the field is essential. Although not discussed in detail in this chapter, we have developed several methodologies to create internal shorts in cells. This section describes the most likely mechanism for initiation of the internal short circuit from metal particle contamination and how we have used internal short implantation methods to investigate that mechanism.

The most likely mechanism for initiation of the internal short involves the formation of a metal dendrite between the anode and cathode. In this process, a metal particle present in or on the cathode (positive) will dissolve by an electrochemical oxidation process, and the resulting metal ions will diffuse to the anode (negative) where they will plate, often over an extended period of time and many charge/discharge cycles, resulting in the formation of a metallic dendrite that eventually makes a durable electrical contact back to the cathode and shorts the cell. In the field, the exact location of the short in a cell is also a critical factor with respect to occurrence of thermal events. We have confirmed this mechanism by implanting particles of iron and nickel in Li-ion cells.

Figure 2 provides experimental evidence supporting this mechanism. The top left panel of Fig. 2 illustrates a cell constructed with a large (oversized relative to particles implicated in field-failures) nickel particle with thickness of either 50 or 100 μm placed on the cathode current collector. The bottom pane of Fig. 2 shows the subsequent cycling of this cell to the point of development of an internal short. Postmortem examination of the cell was very instructive. The top right panel of Fig. 2 shows deposits of plated metal adhered to the separator. Inspection of both sides of the separator shows that the deposit's area is larger on the anode side than on the cathode side, clearly indicating the direction of its growth from the anode to the cathode. Furthermore, EDAX of the anode itself shows deposition of nickel on the anode, which of course was not present prior to cell assembly. Taken together, these results clearly show the operative mechanism for formation of internal shorts. Metal particles on (and possibly in) the cathode dissolve and plate out on the anode, growing back through the separator, leading to an internal short.

It is not surprising that a nickel metal particle present in the cathode would result in shorting of the Li-ion cell. The standard potential for Ni/Ni^{2+} is 2.9 V (vs Li/Li^{+}), implying that Ni will dissolve at typical cathode potentials >3.5 V (vs Li/Li^{+}) and plate at typical anode potentials <1.5 V (vs Li/Li^{+}). Similar behavior is also expected of Fe; the standard potential for Fe/Fe^{2+} is 2.6 V (vs Li/Li^{+}). Separate cyclic voltammetry experiments on Ni and Fe foils in Li-ion battery electrolytes also confirmed this mechanism. This mechanism also explains why internal shorts can develop even on open circuit and explains how the shorts can "grow" over time and not be present for some time after manufacture of the cells. Plating and dendrite growth is a stochastic process, and induction of the overall cell shorting process is also likely to be so. Thus, several factors can limit the rate of dendrite growth and probably even its occurrence.

It has also been experimentally confirmed that metal particles placed on the cathode in 18650 cells can cause internal short circuits capable of inducing thermal runaway (sample result shown in Fig. 3). These experiments will be detailed in a future publication. Using this sort of test platform, the resistance of shorts and the evolution of that resistance during tests can be estimated. It has also been possible to evaluate variations in behavior of various metals and variations in the nature of deposits formed with different metals. Judicious placement of particles can also lead to short formation and cell failure after multiple charge/discharge cycles (as opposed to during the initial charge). The delayed short formation facilitates efforts to identify precursor signals that can warn of development of an internal short in the field.

Several factors can determine how a short might grow from a foreign metal particle, and hence

Lithium-Ion Batteries, Safety. Figure 2

Internal short formation in a coin cell. Photographs in the *top left panel* show the coin cell construction for these tests. A crescent-shaped Ni particle was placed on a scraped-off portion of the positive electrode. The cycling data on the bottom panel show the formation of an internal short circuit in the cell during normal charge/discharge cycling, for two different thicknesses of the Ni particle (two different coin cells for each particle thickness). The photographs in the *top right panel* are of the separator from one of the coin cell tests. The metal deposits can be clearly seen. The cathode active material was $LiCoO_2$, the separator was Celgard 2325, and the anode material was MCMB2528

determine the magnitude and rate of local i^2R heating as the cell discharges through the short circuit. These factors include: the nature of the metal, the size and shape of the particle, the rate capability of the cell, separator permeation and thermal properties, charge/discharge history of the cell, and temperature distribution/history. At this moment, there is insufficient experimental data to comment on the relative contributions of these factors in determining the rate and magnitude of heat release through the short circuit. However, we are performing specially designed experiments to probe these factors and will discuss some of them in a forthcoming publication.

Other Possible Mechanisms of Internal Shorting

There are various ways in which an apparently normal cell might develop an internal short in the field [39, 40]. However, the nature of the internal shorts formed by these different routes, and the extent to which they may or may not be likely to induce thermal runaway, might be very different. Mechanisms cited in the literature or generally discussed by battery engineers that implicate foreign metal particles are summarized below:

- *Lithium deposition/dendrites* form during cell operation for a number of possible reasons, including charge processes that drive the anode to the lithium

Lithium-Ion Batteries, Safety. Figure 3

Response of an 18650 cell following deliberate implantation of a metal particle on the cathode of the cell. In this experiment, a fully discharged commercial 18650 cell was removed from its can. The jelly roll was partially unwound, and a metal particle was placed on the cathode side. The jelly roll was then placed in a suitably sized can and normally cycled. The cell experienced thermal runaway during normal charge/discharge cycling

potential or as a result of lithium imbalance in the cell. Unintentional overcharge due to a faulty BMU can also result in lithium deposition on the anode, with repeated overcharging leading to lithium dendrite growth. There is also evidence reported for foreign metal particles on the anode surface serving as nucleation sites for lithium deposition. There is no doubt that lithium deposition occurs in lithium-ion cells under a variety of circumstances. We suspect that lithium dendrites can lead to internal shorts, resulting in premature cell failure. However, lithium dendrites are less likely to dissipate sufficient power to enable thermal runaway than are dendrites of higher melting point metals. Our simulations show that the temperature of the dendrite itself can significantly exceed the melting temperature of lithium metal (180°C). Hence, it is less likely that lithium deposits/dendrites could support powers similar to those possible with metal contaminants such as Ni or Fe (melting temperatures >1,400°C).

- *Particle migration and separator puncture.* A metal particle in the cell (presumably in/on the anode) can migrate somewhat as a result of the volume changes that occur during charge and discharge and can translate sufficiently to pierce the separator and create a short. In this mechanism, the nature of the contact between the metal and the cathode could potentially be quite different from that in the mechanism of metal particle dissolution at the cathode followed by plating back to the cathode from the anode. A complex question raised by the formation of internal shorts by metal particles (and a probable driver of the process's highly stochastic nature) is how a durable contact is eventually established between the high voltage cathode and the relatively easily oxidized and dissolved metal. In the dissolution/plating mechanism, the growing dendrite might contact some of the original metal particle remaining on and contacting the cathode, and furthermore, the ongoing dissolution/plating process could result in multiple and repeated contacts being made between the growing dendrite and the cathode, providing many opportunities for a durable short to be established. The mechanism of particle migration and separator puncture might be less likely to yield a durable cathode contact that is capable of supporting a thermal runaway-inducing power dissipation level.

- *Lower power particle short induces separator melting, creating a higher power short.* It has been postulated that a small particle-based internal short, rather than itself dissipating sufficient power to stimulate thermal runaway, generates only enough heat to cause localized separator melting and a larger area face-to-face interelectrode short. This larger short then stimulates thermal runaway.

A number of technologies have been developed to address some of the above scenarios. High puncture strength and high melt strength separators have been developed. Numerous organizations across the battery industry have elected to deploy ceramic layers, implemented as porous coatings on electrodes or separators in cells, as a means of enhancing lithium-ion battery safety. Although such efforts may be effective in preventing the separator puncture or melting scenarios, there is a danger in viewing them as a panacea. These separators and ceramic layers are all necessarily highly porous (otherwise they will compromise a cell's performance), and so the mechanism of particle dissolution and growth of dendrites to the point of internal shorting will still be operative. In our limited testing of cells containing ceramic layers, we have indeed observed formation of internal shorts, including those that mature to thermal runaway, in cells that have been seeded with a particle on the cathode. Therefore, technologies such as ceramic layers may lessen the frequency of internal short occurrence but should not be viewed as eliminating the problem.

Factors Influencing Thermal Runaway from Internal Shorts

As we described earlier, an internal short circuit can cause the local temperature to rise "in the vicinity" of the short, which then stimulates additional heat release due to exothermic anode reaction with electrolyte and cathode reaction with electrolyte. Whether or not thermal runaway follows from such an internal short is a particularly complex problem because:

1. An internal short initiates with a highly nonhomogeneous temperature distribution in the cell due to heat generation in a very small area (a "hot spot")
2. Local temperatures get high enough, fast enough to stimulate exothermic decompositions on a local basis
3. Whether thermal runaway follows from this nonhomogeneous temperature profile is determined by a complex interaction among instantaneous values of temperature, concentrations, and rates of reactions, as well as applicable heat transfer both within the cell and out of the cell through its surface

Simulations allow us to understand this complicated relationship and to identify the critical parameters that can alter this relationship to prevent thermal runaway.

Model Description

We have developed a model that is capable of fully three-dimensional, transient simulations of the thermal response of the cell following an internal short circuit. The model employs a commercial finite element analysis (FEA) code, Abaqus, augmented with our own subroutines. Key features of the model are highlighted in Fig. 4. Abaqus was augmented with subroutines for calculating local heat generation from the short circuit and from anode and cathode decomposition reactions. An effective model must consider not just the total heat release which was discussed earlier but also the kinetics (how fast can the heat be released?). Kinetics submodels for heat generation can be derived from differential scanning calorimetry (DSC) or accelerating rate calorimetry (ARC) measurements of charged anode and cathode materials in contact with standard electrolytes. The measurement techniques and conversion to useful kinetic rate expressions will be detailed in a future publication. The model also incorporates representative thermal properties (specific heat, thermal conductivity, density) for the various components of the Li-ion cell. These were either measured in our labs or taken from the published literature (including Refs. [41, 42]). Dissection of state-of-the-art 18650 cells provided estimates of cell properties such as weights of anode and cathode materials, current collector dimensions, can dimensions, etc. The model also incorporates a submodel for separator shutdown kinetics and is being augmented to incorporate a submodel for electrochemical

Lithium-Ion Batteries, Safety. Figure 4
Key features of our FEA model to simulate thermal runaway of Li-ion cells

kinetics and pressure, including pressure release from the local temperature rise and decomposition reactions.

The model allows the internal short to be placed anywhere in the cell and typically represents the short as a constant power, localized heat source that acts for a specified period of time. (The ability to terminate the short after an arbitrary period of time is a unique and valuable benefit of a model, for reasons revealed below, that is not available in actual short circuits). Surface heat transfer coefficients and ambient temperatures are specified as boundary conditions. The initial cell temperature is also specified. The transient heat transfer model calculates and keeps track of the local values of temperature, species concentrations, extents of reaction, and heat generation rates at every time step. The model can be two-dimensional or fully three-dimensional, depending on the degree of symmetry afforded by the geometry of the cell and the conditions that are being evaluated, such as the location of the short. For example, for an 18650 cell, if the short is near the center of the cell, the results of a two-dimensional, axisymmetric model are essentially the same as those of a fully three-dimensional analysis of the same conditions. This opportunity for simplification is not available for a short that is located near the outer surface of the jelly roll.

Thermal Runaway Induced by an Internal Short

The following sample simulation illustrates the progression of thermal runaway following an internal short circuit. Consider an 18650 cell which has a 10-W internal short circuit starting at time t = 0 near the center of the cell, and lasting for 1,410 s in this simulation. For this two-dimensional, axisymmetric simulation, Fig. 5 shows the time dependence of temperature in the vicinity of the short and at the cell surface (midway between the top and bottom of the cell). Figure 6 shows the temperature distribution in the cell at select times, and Fig. 7 shows the cumulative heat release and extent of reaction for the anode and cathode decomposition reactions. A surface heat transfer film coefficient of 10 W/m^2-K was employed,

Lithium-Ion Batteries, Safety. Figure 5
Temperature history in the vicinity (~2 mm away) of the short circuit and at the can surface for a 10-W short circuit that is active for 1,410 s in a 2.6-Ah 18650 cell

corresponding to nearly quiescent ambient conditions. The initial temperature and ambient temperature were both set to 20°C.

The results shown in Figs. 5–7 can be considered in terms of three distinct time periods. In the first time period, the temperature in the vicinity of the short circuit is higher than that at the outer extremities of the cell, owing to heat generation from the short circuit (which has been placed near the center of the cell). The internal short is a localized heat source, or hot spot. In practice, this heat source can be driven from other cells in the battery pack or just from the shorted cell itself in the case of an isolated cell. In addition to electrical heating, heat release from the anode and cathode decomposition reactions, occurring wherever critical onset temperatures in the cell have been exceeded, also contributes to the temperature rise. As shown in Fig. 6, the iso-temperature contours are oblong in this

Lithium-Ion Batteries, Safety. Figure 6
Temperature distributions corresponding to the simulation in Fig. 5 showing the progressive change in temperature in a cell following the formation of an internal short circuit that leads to eventual thermal runaway

Lithium-Ion Batteries, Safety. Figure 7
Cumulative heat release (plot on the *left*) and the extent of reaction (plot on the *right*) for the anode and cathode decomposition reactions, corresponding to the simulation results in Fig. 5

time frame due to significantly higher thermal conductivity in the axial direction of the jelly roll compared to the radial direction.

Once the short power is reduced to zero at 1,410 s, the cell temperature quickly becomes uniform, as heat transfer internal to the cell equalizes the temperature within the cell.

In the second time period (from about 1,410–2,000 s), there is no longer a contribution from the local heat source because the internal short has been turned off. The temperature continues to increase, albeit at a much slower rate. In this time frame, the rate of heat release from the decomposition reactions is only slightly higher than the rate of heat loss at the cell surface, resulting in a gradual rise of the cell temperature. As can be seen from the results in Fig. 7, it is primarily the exothermal anode decomposition reactions that contribute to this heat release; the energy contributed from the cathode decompositions is insignificant in this time frame. The anode decomposition reactions assume a triggering role because their rates (and hence the associated heat release) become significant at a lower temperature than the cathode decomposition reactions, and hence, the anode reactions proceed to a greater extent than the cathode reactions in this time frame. The particular example and corresponding set of conditions being discussed here have been chosen to illustrate a condition in which a sufficient percentage of the material in the cell has been elevated to a temperature that is just above the "point of no return" on the path toward thermal runaway. In an equivalent simulation in which the internal short is turned off just 10 s sooner at 1,400 s, discussed below and shown in Fig. 8, no thermal runaway ensues. The substantial length of time for which an internal short can be active prior to inducing thermal runaway suggests that there may be sufficient time to intervene and prevent a thermal runaway if adequate signals indicating development of an internal short can be identified.

In the third time period, beyond about 2,000 s, the cell begins to heat up dramatically and goes into thermal runaway. Self-heating of the cell accelerates because the rates of the anode and cathode decomposition reactions accelerate with rising temperature and because the extent of active material in the cell that contributes to this heat generation also increases. The combination of these factors results in an unstable increase in temperature which is known as thermal runaway. The rapid rise in temperature is roughly what witnesses report when they have been in proximity to lithium-ion field-failures. Note not only the very rapid rise in temperature in Fig. 5 once thermal runaway has initiated, but also the general range of temperatures that are realized as a result of the runaway. The latter reflects the general range of temperature

Lithium-Ion Batteries, Safety. Figure 8

Simulated temperature profiles for two conditions where thermal runaway does not occur. The plot on the left corresponds to the case where a 10-W short was active for 1,400 s. The plot on the right corresponds to a short power of 3.5 W, which was active until the cell completely discharged through the short circuit without causing thermal runaway

known to occur in safety incidents because of the evidence (previously cited) that is obtained from cell postmortems.

The above discussion illustrates the complexity of thermal runaway induced by an internal short. Furthermore, the rapid rise in temperature at ~2,000 s illustrates one of the reasons that material-level heat release from DSC or ARC measurements by themselves are not likely to be relevant predictors of relative safety of various cathode materials. Note how in Figs. 6 and 7 the progression to a thermal runaway is inevitable beyond about 1,410 s, at which point the short has been turned off in this simulation, and note how the cell quickly traverses a wide range of temperatures (in this case, from about 150°C to about 550°C) as runaway proceeds.

As mentioned above, this model has also been used to explore the conditions under which thermal runaway will not occur. Figure 8 shows results for two conditions where thermal runaway does not occur. The figure on the left corresponds to a 10-W short, otherwise identical to the one depicted in Fig. 5, which is active for 1,400 s, whereas the figure on the right corresponds to a 3.5-W short that is active until the cell completely discharges through the short. All other conditions are identical to the simulations corresponding to Figs. 5–7.

Comparing the results in Fig. 5 with the left hand plot of Fig. 8 shows that the energy dissipated in the short is a key factor in determining thermal runaway. Essentially, when the 10-W short is active for 1,400 s (Fig. 8), thermal runaway does not occur. But when the 10-W short is active for only 10 s longer (Fig. 5), thermal runaway occurs. Thus, there is a minimum energy (or "threshold energy") that must be dissipated in the short before thermal runaway will occur. The specific value of that threshold energy is related to cell design, materials employed, and operative heat transfer conditions. Of course, slight variations in any of these parameters might result in a different threshold energy.

The right-hand plot in Fig. 8 shows a case in which short power has been reduced in successive simulations until thermal runaway does not occur no matter how long the short is maintained in an active state (a "threshold power"). Note the parallel lines in Fig. 8 beyond about 5,000 s, corresponding to the state in which the rate of heat generation in the cell is exactly equal to the rate of heat loss from the outer surface of the cell. Since the experiment is bounded by the total energy of the cell, the short essentially terminates when there is no capacity remaining in the cell. As can be seen in the figure, the cell temperature then decays to room temperature.

The Concept of a "Safe Zone"

The results presented in Figs. 5, 7, and 8 have been chosen from a larger number of simulations because, in combination, they illustrate how a new figure can be constructed from simulations to demarcate a "Safe Zone" for a given cell construction and cell materials and for the associated heat transfer conditions. Figure 9 illustrates the construct for a generic 18650 cell. In this figure, various short powers are represented on the x-axis. The y-axis corresponds to the relative energy dissipated in the short as a percentage of the total electrochemical energy in the cell.

Figures 5, 7, and 8 represent conditions that can be placed on this chart. The 10-W short begins at t = 0 corresponding to zero energy release on the y-axis and moves vertically with increasing time. At 1,400 s, there has been insufficient energy input to stimulate a thermal runaway, but at 1,410 s, thermal runaway ensues. A threshold energy has been exceeded. Running a series of such simulations, a family of such situations can be constructed, demarcating a threshold energy curve on the plot.

Similarly, Fig. 8 (right) has already demonstrated existence of a threshold power below which no thermal runaway is possible, no matter how long the short is in place. The existence of a threshold power implies that there will be a finite range of short resistance capable of dissipating sufficient localized heat to stimulate thermal runaway. If short resistance is above this critical range, insufficient current is supplied to the short. The critical short resistance range will be defined by the characteristic of the cell and pack.

Note in Fig. 9 how the threshold energy curve rises sharply as short power is reduced to values approaching the threshold power. The resulting cross-hatched area is a "Safe Zone." Internal shorts with power or energy characteristics within this region will not induce thermal runaway. In practice, the threshold power is a more critical parameter, since in the field there are no practical means to interrupt an internal short once it has been initiated. Implications of the threshold energy curve's shape will be discussed in a future publication.

Note that a "Safe Zone" plot can be constructed for any lithium-ion cell, representing the particular cell size and design (i.e., form factor, capacity, electrode dimensions, etc.) and materials employed, as well as the particular heat transfer conditions that apply. One can use

$$RE = \frac{E_s}{E_e}$$

RE: Relative Energy

E_s: Energy dissipated in the short

E_e: Electrical energy stored in the battery

Lithium-Ion Batteries, Safety. Figure 9
The Safe Zone construct

Safe Zone plots to compare the relative safety of various cells and/or materials, as well as to evaluate the relative safety of cells under various heat transfer conditions.

Illustrative Applications of the Safe Zone Concept

The Safe Zone concept allows a quantitative assessment of safety in a way that has not previously been possible. There are numerous ways that the Safe Zone concept may be employed, including as a tool to design safer cells, to assess the safety impact of various system design changes, to assess the impacts of various materials changes, and to consider the relative risk of cascading in a battery pack. The following describes an example of one such use of the Safe Zone concept.

In the last few years, there have been multiple discussions regarding the relative safety of cylindrical cells versus prismatic cells. The subject is attracting a great deal of attention with respect to transportation applications. It has generally been accepted that prismatic cells are safer and will allow superior cooling. But how can this advantage be quantified, and how can it be linked to cooling conditions as well as cooling requirements? The Safe Zone concept, and the associated concept of a threshold power, provides the necessary quantitative basis to allow these problems to begin to be assessed as engineering issues, rather than as a matter of intuition.

Cylindrical and prismatic cell designs with identical capacity (33 Ah, as might be used in PHEV applications) were modeled with identical internal short circuits to assess the threshold power parameters. Figure 10 illustrates the cell designs.

Initial cell temperature was set at 20°C, the surface heat transfer coefficient was set for both cells at 10 W/m^2-K, and the short was assumed to be located near or at the middle of each cell. Simulations were carried out for various short power levels in order to understand and quantify the power levels associated with safety events in these two cells. Figure 11 illustrates the results for an internal short of 12 W, in particular showing the rapid transition of temperatures throughout the cylindrical cell over the critical few seconds when the cell goes into thermal runaway. Similarly, Fig. 12 illustrates the temperature transitions in the prismatic cell with a 53 W internal short around the time at which thermal runaway occurs. Figures 11 and 12 illustrate the rapid temperature increase that accompanies thermal runaway for both cell types;

Lithium-Ion Batteries, Safety. Figure 10

Lithium-Ion Batteries, Safety. Figure 11

Temperature distributions at selected times following a 12-W internal short circuit in the cylindrical PHEV cell

Lithium-Ion Batteries, Safety. Figure 12

Temperature distributions at selected times following a 53-W internal short circuit in the prismatic PHEV cell

Lithium-Ion Batteries, Safety. Figure 13
Calculation of cell surface temperatures for the cylindrical and prismatic PHEV cells near the threshold power conditions

however, the actual times and short power associated with thermal runaway in these two cell types are quite different.

Figure 13 compares data for the two cell types. For the cylindrical cell, note that a short power of 11 W does not lead to thermal runaway, even at very "long" times. Comparison with the prismatic cell is instructive. For the prismatic cell, with identical capacity and an identical heat exchange environment, a short power of 51 W does not lead to thermal runaway. Short power must be increased to 53 W before a thermal runaway is observed. Thus, a quantitative methodology to evaluate the relative safety of these two cells is demonstrated. The prismatic cell provided a resistance to thermal runaway that is several factors greater than that for the cylindrical cell. Since these calculations incorporate quantitative consideration of the heat transfer conditions, a pathway is available by which it is possible to design a cooling system to prevent thermal runaway events from taking place.

Figure 14 illustrates another use of the Safe Zone construct and the concept of a threshold power. In this assessment, simulations were performed for two otherwise identical 2.6-Ah 18650 cells having different anode materials: one with MCMB 2528 (25 μm mean diameter, low surface area), and one with MCMB 628 (6 μm mean diameter, high surface area). The surface heat transfer coefficient was assumed to be 11 W/m^2-K. The FEA model for this particular set of simulations also accounted for the kinetics of separator shutdown. In this simulation, the short, rather than being modeled as a constant power source, is represented as a constant 25-mΩ resistance in series with the cell's 50-mΩ equivalent series resistance. The total power dissipated in the cell due to the short (both i^2R heating in the short and Joule heating in the jelly roll) was calculated as 220 W initially. The total power dissipated in the short was then set to decrease with time based on a function that includes the relative volume of the jelly roll in which the temperature had risen past the point at which the separator would shut down (130°C).

The right hand charts in Fig. 14 show DSC data for these two anode materials and the associated anode models that were employed in the simulations. The results of the simulations are shown on the left hand side of the figure. The results are striking – a simple change in anode material has a dramatic impact on the safety of this cell, with the cell employing MCMB 628 going into thermal runaway while the cell employing MCMB 2528 does not. DSC data on the

Lithium-Ion Batteries, Safety. Figure 14
Simulation results showing the effect of the choice of anode material on thermal runaway. The plot on the *left* shows the cell surface temperature time dependence for two different anode submodels

right of Fig. 14 suggest the reasons for this result. The MCMB 628 shows significantly higher heat release between 100°C and 200°C than the MCMB 2528. This example shows the extent to which the anode material acts as the trigger for thermal runaway when internal shorts and field-failures occur. Furthermore, the cell surface temperature profiles on the left side of Fig. 14 illustrate another critical factor that is not well appreciated: the cell transitions rapidly into thermal runaway well below 200°C – well before any significant exothermic decomposition of cathode material has taken place.

Differences Between Abuse Tolerance and Field-Failures

The distinction between abuse tolerance and field-failure (internal shorts) is important for a number of reasons. It helps bring into focus the extent to which historic testing for safety is focused on abuse testing, even though the actual safety events that occur in the field are quite different. From a mechanistic perspective, the triggers are fundamentally different and the resulting responses are different. The general distinctions between abuse tolerance and field-failure are summarized in Fig. 15 and discussed below.

Field-failures are overwhelmingly attributable to internal short circuits that occur during otherwise "normal" operation, i.e., there is no external abuse or trigger. In contrast, heat exposure or forced overcharge are examples of an external abuse driving a potentially unsafe situation. The response to these abuse conditions should be identical for all cells of the same cell design employing the same materials.

In response to most abuses (note that penetration- and impact-based abuses are exceptions), a cell's temperature throughout an abuse is homogeneous, until the cell fails or the abuse is terminated. All cells of the same cell design and same materials should respond to an abuse in a roughly identical manner. In contrast, field-failure involves a nonhomogeneous temperature distribution in a cell's response to an internally driven trigger – the internal short, or hot spot.

The internal short represents a particularly insidious failure mechanism not only because it takes place during otherwise normal operation but also because it is self-driven and cannot be protected against by typical safety protection devices such as PTCs, CIDs, etc. It is also how most safety incidents are initiated in the field,

Abuse Tolerance	Field Failures
Predictable	Not predictable, no warning
Common to all cells	One-in-a-million (or less)
Can/should be evaluated at the cell level by standard tests	Difficult to evaluate at the cell level, or through QC
Various chemistries can/should be evaluated for relative abuse tolerance	Cell temperature is non-homogeneous, starting with "hot spot"
Time constants relatively long, entire thermal mass of cell is heated uniformly	Much higher temperatures can occur *quickly, locally*
Can be augmented by protection devices	PTC, CID, shutdown separators, electronic controls are not effective – problem is internally driven.
Externally-driven	

Lithium-Ion Batteries, Safety. Figure 15
Summary of the key differences between abuse tolerance and field-failures

and yet the battery industry does not have adequate tests to "predict" the risk for such failures.

The lack of availability of suitable tests for the internal short should not be a surprise – any event that takes place rarely, is stochastic *and* exhibits some form of incubation process, arguably does not exhibit a detectable precondition at the point of manufacture and certainly does not exhibit a predisposal to the problem *in every cell*. Thus, the practice of removing a few cells from the manufacturing line to test for safety is fine for abuse triggers (for abuse tolerance) but is clearly inappropriate as a measure of susceptibility to development of an internal short in the field.

Perhaps most challenging is the tension between the desire of those in the battery community to have a test that they can use to screen cells for field-failure (the internal short) and the statistical impossibility of picking cells to test that have the necessary preconditions for possible internal short-induced thermal runaway, putting aside the issue of the extent to which actual charge/discharge, voltage/time, and temperature effects may impact the probability of development of an internal short. That tension has led many across the battery and application/user communities to advocate that tests such as nail penetration, round bar crush impact tests, or other custom tests mentioned earlier, be employed to screen cells for tolerance to internal shorts. There are many reasons why this approach is an inappropriate surrogate for field-failure. One reason is that the condition that leads to internal shorts leading to thermal runaway is not present in fresh cells. In addition, it is statistically impossible to identify cells that actually have some form of precondition *and* for which that precondition has matured to the point at which an internal short exists. Most importantly, the nature of the internal shorts produced in such tests is nothing like that of the shorts involved in field-failures. These abuse tests often involve multiple shorts and hard shorts; conditions that are not representative of how internal shorts occur in the field. Both modeling and actual observations have shown that a number of different variable parameters can be critical to whether a given short will cause runaway in a given cell, and thus, the possibility of thermal runaway is a complex, multidimensional response surface. The single protocol, "one size fits all" approach of internal short circuit abuse tests means that such tests fix a number of these parameters and can therefore be gamed. Thus, relative safety under internal short circuit abuse test conditions is not likely to be relevant to the tendency for field-failure.

Nevertheless, the nail penetration test, the round bar crush test, and the drop test do reflect potential triggers (in this case, abuses) that must be considered, especially for transportation applications. In such applications, it is easy to imagine impact conditions that might lead to multiple internal shorts in cells. It is

clearly desirable to understand the tolerance of cells to such abuses. The challenge, however, is to understand how representative such tests may be for the wide variety of impacts (speeds, angles, penetrations, etc.) that might occur in the field (putting aside the issue of potential gaming of the tests). Similar problems have been addressed with regard to transport of large quantities of flammable liquid in vehicles' gasoline tanks.

This abuse tolerance versus field-failure framework is also a useful way to characterize testing work carried out by various researchers, or tests that purport to address safety. For example, various tests can be assessed with respect to whether they reflect or measure a property of all cells of the same design and materials (an abuse), or whether they reflect a rare condition that develops after time in the field.

An Overall Framework for Consideration of Li-Ion Battery Safety

The fact that lithium-ion field-failures (1) are so rare, (2) cannot be completely eliminated, and (3) can cause severe damage has led us to develop an integrated framework for development of lithium-ion battery safety technologies. The framework is especially important in transportation applications. It is clear that field-failures continue to occur in portable computer applications (multiple CPSC and newspaper references can be found) and seem to attract only modest attention. However, a single field-failure in a PHEV or EV is likely to be more violent and represents greater threat to human safety. Thus, it is highly desirable to develop means to assure that such field-failures do not occur and that their impact is minimized.

The overall framework is depicted in Fig. 16 and advocates that several categories be employed to consider lithium-ion safety technologies. These categories help organize specific approaches. First are technologies that preempt thermal runaway, examples of which might include specific cell designs or specific separator types. Next, technologies to detect the earliest stages of development of internal shorts might, for example, involve identification of specific electrical signals and the use of specific sensors. Detection can be of value only if accompanied by access to effective means for intervening and preventing development of a full-blown thermal runaway. When all else fails, it is still very desirable to confine thermal runaway to just a single cell, namely to prevent cascading phenomena.

Figure 16 also captures the difficult challenge of validating any new safety technology that is developed. How can one validate a safety technology intended to address events that occur on the order of once for every 5–10 million cells without producing and testing many

Lithium-Ion Batteries, Safety. Figure 16
Framework for consideration of Li-ion battery safety technologies

millions of cells? The challenge is fundamental, and thus, it is important to have available means of producing cell/battery failures that are arguably "similar" to those that occur in the field. For these reasons, verification of the failure mechanism is also important.

Future Directions

Abuse tolerance in lithium-ion cells is critical to public safety, and a number of screening tests for lithium-ion cells and batteries have been devised. Battery developers and users then test cells and batteries to screen for tolerance with respect to the given abuse, and then design cells and batteries with improved abuse tolerance.

In contrast, safety in lithium-ion cells/batteries requires deliberate new strategies to deal with the possible occurrence of internal shorts that can progress to thermal runaway. These strategies need to recognize the extent to which the safety tests most typically utilized in the battery industry do not reflect the most common and most dangerous mechanism by which safety incidents actually occur in the field – field-failures.

The battery community does not utilize an overall strategy to intervene, for safety's sake, as temperature rises in a lithium-ion cell or battery in advance of a thermal runaway. Although literature publications may consider the relative temperatures at which particular battery materials decompose, there is no consideration given to how these temperatures may be prevented.

The work presented in this chapter clearly shows that when thermal runaway occurs, it proceeds so fast that cell temperature progresses from less than about 150–180°C to over 600°C almost instantly. This result also indicates the fallacy in imputing safety advantages to one battery material that exhibits an onset temperature for decomposition (as captured, e.g., in DSCs) that is somewhat higher than that of another battery material (e.g., a cathode material with an onset temperature of 220°C is suggested to result in a safer cell than one with an onset temperature of 190°C). For example, the assumption is often made that cathode materials with higher onset temperatures will automatically make a cell safer or eliminate safety incidents. This work illustrates why that view has limited validity; first because anode decomposition is generally the lower temperature trigger for initiating thermal runaway subsequent to internal heating generated by an internal short, and second, because higher cathode decomposition temperature can at best increase the threshold energy for inducing thermal runaway (not the threshold power), but cannot eliminate the threat altogether.

Looking to the future, we suggest that abuse tolerance and field-failures be managed as distinct concerns. With both categories, a reasonable strategy involves identifying and pursuing all efforts to prevent the final runaway process from maturing.

In that sense, a new approach to safety should also recognize one additional factor; namely that lithium-ion cells are no longer useful when their temperature exceeds about 100–110°C, and thereafter, they should/must be removed from service. Abuse tolerance can be further enhanced by focusing all efforts on identifying and shutting down all offending safety-related triggers by, for example, discharging the cell as soon as a cell temperature exceeds about 110–120°C. If an abuse/trigger is removed reasonably quickly, the cell simply cools down, and no safety event occurs.

In the case of field-failures (the internal short), this approach does not work because the cell skin temperatures may not reach these levels until thermal runaway is inevitable and/or in progress. Because it can be self-driven, thermal runaway from internal shorts must be detected during charge/discharge cycles prior to the final charge cycle that results in an internal short "mature" enough to lead to a thermal runaway. Therefore, it is imperative to identify early warning signals and to develop sensors that can warn of developing internal shorts well before a thermal runaway initiates and that are capable of integration at low cost into battery management systems.

We hope this chapter encourages the battery community to pursue more fundamental work into safety testing as well as understanding of safety-related processes in lithium-ion batteries. Work is needed to develop more sophisticated models, to measure material properties that contribute to enhanced safety, to develop improved methods of calorimetry, and to develop new safety technologies that will help assure safety of lithium-ion batteries. With greater visibility of the issues, perhaps this field will be taken up in graduate schools as an important topic that should yield rich problems and productive theses.

Acknowledgments

The authors gratefully acknowledge support from the US Department of Energy for portions of this work. In addition, countless discussions with present and past colleagues at TIAX over several years have resulted in many insights regarding battery safety captured in this work. Specifically, the authors gratefully acknowledge Drs. Christopher H. McCoy, Mehmet Rona, Jane Rempel, Ms. Rosalind Takata, Drs. Bookeun Oh, S.K. Singh, Karen Thomas-Alyea, and Per Onnerud. Investigation of various safety incidents also led to very productive discussions with major battery companies and portable product companies which, though anonymous, are gratefully acknowledged.

Glossary

Active material The material in the electrodes of a cell or battery that takes part in the electrochemical reactions of charge or discharge.

Battery/battery pack An assembly of any number of Li-ion cells, associated electronics, battery packaging, and connector(s).

Capacity The total number of Ampere-hours (Ah) that can be withdrawn from a fully charged cell or battery under specified conditions of discharge.

Cell Basic lithium ion unit providing a source of electrical energy by direct conversion of chemical energy that consists of electrodes, separator, electrolyte, container, and terminals, and that is designed to be charged electrically.

Current collector An inert member of high electrical conductivity used to conduct current from or to an electrode during discharge or charge.

Cycle The discharge and subsequent or preceding charge of a Li-ion cell or battery such that it is restored to its original conditions.

Cycle life The number of cycles under specified conditions which are available from a Li-ion cell or battery before it fails to meet specified criteria as to performance.

Electrolyte The medium which provides the ion transport mechanism between the positive and negative electrodes of a cell.

Negative electrode The electrode acting as an anode when a cell or battery is discharging.

Overcharge The forcing of a current through a Li-ion cell or battery pack after it has been fully charged.

Positive electrode The electrode acting as a cathode when a cell or battery is discharging.

Separator An ionically conductive, electronically insulative material which prevents electronic contact between electrodes of opposite polarity in the same cell.

Thermal runaway The cell condition where the internal cell reactions generate more thermal heat than the cell can dissipate. The condition causes cell venting and premature failure.

Definition of the Subject

Lithium-ion battery (LIB) is one of rechargeable battery types in which lithium ions move from the negative electrode (anode) to the positive electrode (cathode) during discharge, and back when charging. It is the most popular choice for consumer electronics applications mainly due to high-energy density, longer cycle and shelf life, and no memory effect. With Li-ion batteries currently gaining much attraction in electric drive vehicle, the concern for global warming and a clean environment may be well served with advances in such systems.

Introduction

During the last 15 years, lithium-ion batteries have dominated the advanced energy sources by powering the modern portable electronics and replaced many other commercial battery systems in the market. The prime reasons for its rapid success and proliferation in consumer electronic market are its superior characteristics over other battery systems, namely, high voltage, high-energy density, and longer cycle and shelf life with no memory effect. The significant progress of Li-ion batteries is mainly due to numerous innovations and advancements in materials, designs, and safety. This entry is intended to provide an overview of Li-ion batteries on several aspects. Starting with a brief discussion on its history, commercial success, and working mechanism, all the critical components inside the cell have been discussed in adequate detail. The later part of this chapter will primarily focus on manufacturing process, recent advances, and modern trends in Li-ion systems and detailed discussion on Li-ion cell safety.

History of Li-Ion Batteries

The working mechanism of Li-ion cells is often related to that of a rocking chair since within the cell, the lithium ions swing between the negative electrode and the positive electrode through an organic liquid electrolyte, like a rocking chair from side to side. This "rocking-chair" concept was first proposed by M.S. Whittingham at Exxon in 1970s where he discovered the concept of intercalation electrodes using titanium(II) sulfide as the cathode and lithium metal as the anode [1]. The principal concept is based on the intercalation reaction and is rather different from other conventional secondary batteries which are based on chemical reactions.

Goodenough was the first to patent $LiCoO_2$ as a lithium intercalation cathode material in 1980 [2] and H. Ikeda of Sanyo was the first to patent an intercalation material in an organic solvent such as graphite in 1981 [3]. S. Basu of Bell Laboratories filed an US patent in 1982, based on his finding of lithium intercalation in graphite at room temperature [4]. I. Kuribayashi and A. Yoshino developed a new cell design using an intercalation carbon anode and a $LiCoO_2$ cathode and filed patents worldwide [5]. In 1991, Sony Energytec Inc. began to produce commercial lithium-ion cells under the leadership of Yoshio Nishi. Bellcore team under the leadership of J. M. Tarascon pioneered the modern concept of "polymer" (soft pack) Li-ion cells [6–9].

Soon after commercialization, the Li-ion battery (LIB) system became a popular choice because of its high-energy density, good performance, and no memory effect as occurred with nickel-cadmium (Ni-Cd) or nickel-metal hydride (Ni-MH) batteries. LIBs have been primarily used for portable electronics, especially cellular phones and notebook computers. Recently, the application area has been extended to power tools, electric bikes, and energy storage systems. Several companies are now working toward adapting the lithium-ion system for use in electric drive vehicle (EDV) applications.

Li-ion cells are being built in many different shapes and configurations—button, flat, rectangular (also referred as prismatic), and cylindrical. The cell components (electrodes, electrolyte, and separator) are designed to accommodate a particular cell shape and design. The separators are either stacked between the electrodes or wound together with electrodes to form jellyrolls, as shown in Fig. 1. Typical safety features included in cells with metal enclosure are the PTC and CID devices that are usually

Lithium-Ion Battery Systems and Technology. Figure 1
Typical Li-ion battery configuration: (**a**) spirally wound cylindrical cell, (**b**) wound type prismatic cell

incorporated into the cell top plate and seal. The PTC is a positive temperature coefficient device that changes resistance at a set temperature or current flow and stops a thermal runaway condition from developing. The CID is a current interrupt device that is incorporated into the cell cap, and it interrupts the electrical connection between the cathode tab and the positive terminal when the internal pressure in the cell reaches a given pressure. Another safety feature present in Li-ion cell is the cell vent which activates at pressures just higher than the CID to release the volatile solvent and stops cell action.

Commercial Success

The battery industry has seen enormous growth over the past 15 years in portable, rechargeable battery packs. The majority of this surge can be attributed to the widespread use of cell phones, laptop computers, tablet PCs, video games, and other wireless electronics. At present, this technology is gaining worldwide attention as a battery option for transportation applications, including electric drive vehicles namely HEVs, PHEVs, and BEVs.

The higher volumetric and gravimetric energy storage capability are key characteristics of the Li-ion battery system compared to the conventional sealed nickel-cadmium (Ni-Cd), nickel-metal hydride (Ni-MH), and valve-regulated lead acid (VRLA) battery systems. Figure 2 presents the energy density and specific energy comparisons of small sealed rechargeable battery systems. Some of the distinct advantages of Li-ion system over other commercial rechargeable systems are the choice of chemistry with highest energy and lightest weight, good cycle life, no memory effect, higher energy efficiency, and better high rate capability. Of course there are also certain issues for Li-ion system similar to any other high-energy storage devices that include higher charging times, thermal runaway concerns, relatively more expensive, and requiring advanced protection circuitry for safety and to prevent overcharge and over discharge.

Based on a recent report on rechargeable battery markets that Global Industry Analysts (GIA) announced, the global market for rechargeable batteries is forecast to reach US$16.4 billion by the year 2015 [10]. Factors driving the market growth include growing consumer acceptance of rechargeable battery technologies in various parts of the world, rapid growth in the

Lithium-Ion Battery Systems and Technology. Figure 2
Volumetric energy density (Wh/l) and gravimetric energy density (Wh/kg) for major rechargeable battery systems

electronics market, and increasing role of rechargeable batteries in the automotive sector. It should be noted that in 2006, the market size of rechargeable battery systems for portable power applications was around US $6 billion out of which Li-ion comprises 75% of the market.

The market survey reports show that the lithium-ion battery is becoming an almighty rechargeable system and in 2010, a whopping sum of around 3.9 billion cells has been supplied all together by cell manufacturers around the world which is about two-fold increase in supply compared to 2006 [11] and the supply is expected to grow by at least 15% during 2011. There is a steady increase in the demand for lithium-ion batteries for all portable electronic devices (almost 100% of cell phones and notebook PCs), and in addition, the Li-ion system also started penetrating more and more in other arenas like power tools, energy storage systems (ESS), and so on. Li-ion system now starts competing with Pb-acid systems in the energy storage systems arena primarily due to its superior cycle life and higher columbic efficiency. For the automotive applications, lithium-ion cells have become a hot topic and are now on the verge of being brought on board vehicles on a massive scale. Although the Li-ion battery for HEV application still has little experience in the real market, research and development activity for it is very dynamic at present worldwide. This fact must surely reflect the common recognition that the technology is one of the most promising for the HEV battery of the coming generation. It is predicted that the HEV will be significantly widespread by 2015 and is expected to take a certain portion of the application market at that time.

The tremendous progress in Li-ion cells is clearly visible with as much as a twofold increase in the volumetric and gravimetric energy density combined with a 50% reduction in price was achieved between 1995 and 2006. Figure 3 depicts the increase in capacity of the cylindrical 18650 cell (18 mm in diameter and 65.0 mm long) from 1992 to 2006. In 1995, an 18650 cell with a capacity of around 1.5 Ah was sold for $8, while in 2006, the same size cell with 2.6 Ah sold for about $4. The early LIBs had a capacity of 800 mAh and an end-of-charge voltage of 4.1 V. The initial cells used hard-carbon anode materials which had a capacity of about 200 mAh/g, and the $LiCoO_2$ had a capacity of nearly 110 mAh/g due to 4.1 V charging voltage. In 2003, the capacity of the 18650 cell reached 2.4 Ah. This corresponds to an energy density of over 200 Wh/kg or 500 Wh/L, respectively. These values were reached in part by increasing the cell-operating voltage higher than 4.2 V due to the availability of improved graphite anode materials, electrolyte additives, and a stabilized $LiCoO_2$.

Lithium-Ion Battery Systems and Technology. Figure 3
Capacity (Ah) increase for 18650 lithium-ion cell resulting from advances in active materials and functional additives to electrolyte

The cell producers accomplished the performance improvements through engineering improvements in cell design, new electrode materials, and automated high-speed production to reduce the cost. The capacity of the 18650 cell had reached 2.9 Ah in 2007 based on treated graphite anode and planar-nickel-based cathode and with several kinds of electrolyte additives [12]. With further continuous improvements in all the cell components that includes silicon alloy–type anode materials, lithium-nickel-cobalt-aluminum and nickel-manganese-cobalt cathode materials, novel electrolyte and/or additives, some cell manufacturers are currently able to achieve a maximum capacity of up to 3.4 Ah for the same 18650 cell design.

The major Li-ion cell manufacturers are from Japan, China, and S. Korea. Figure 4 presents the global market share for bare cell shipment volumes from the three countries cell manufacturers for the consumer portable power applications in 2010. Some of the major cell manufacturers include Sanyo, Sony, and Panasonic from Japan; Samsung SDI and LGChem from Korea; and BYD, ATL, and Lishen from China. Figure 5 shows the split-up of small format LIBs supplied for portable power applications namely mobile

Lithium-Ion Battery Systems and Technology. Figure 4

Lithium-Ion Battery Systems and Technology. Figure 5 Movements in cell shipment volumes for each lithium-ion battery application globally in 2010

computing, mobile communications, and other consumer electronics including power tools during 2010. The thin, rectangular polymer/laminate cell construction has been found increasingly favorable in the modern portable consumer electronics market (e.g., Iphone, Ipad smart phones, and so on). Overall, for the consumer electronics market sector, Japan and Korea dominates the production of 18650 type cells and China dominates in prismatic type cell production. There are no major Li-ion manufacturers in the United States or in Europe, even though they constitute large markets for devices powered by Li-ion batteries [13]. Production activity in the United States so far is limited to companies that supply the niche medical and military markets.

There are many emerging market opportunities for Li-ion cells in transportation. Li-ion batteries can provide very high power and are therefore a good candidate for EDV applications. The automotive power market is viewed as the largest future growth opportunity for Li-ion batteries. Their high voltage, low weight, small volume, and potentially long life make them very attractive. Different cell designs and geometries are currently being adapted by cell manufacturers for automotive applications. A few common designs include rectangular flat pouch cell and larger cylindrical cell design.

The cell's capacities for EDV applications are in the range of 25–100 Ah. The typical energy requirement for plug-in hybrid electric vehicle (PHEV) is between 5 and 20 kWh and for all electric vehicle (EV), the energy requirement is more than 20 kWh with a voltage of 300 V or more. A number of modules with energy in the range of 1–2 kWh are necessary. The advantage of Li-ion over Ni-MH for hybrid electric vehicle (HEV) applications that has an energy requirement in the range of 3–5 kWh is still quite not clear, but with decreasing cost as production volume increases, Li-ion cells are considered to be economically competitive. Once Li-ion system finds its place, the transportation market could dominate over the present portable device market.

Principle Behind Li-Ion Batteries

Lithium-Ion Cell

The primary functional components of a typical Li-ion cell are negative electrode (or anode), positive electrode (or cathode), and electrolyte. Most commonly used negative electrode materials include hard carbon, graphitic carbon, and treated graphite. Typical positive electrode materials may include a layered oxide (lithium cobalt oxide, lithium nickel oxide), spinel (like lithium manganese oxide), or a polyanion (such as lithium iron phosphate). The electrolyte in general contains lithium-containing salt such as lithium hexafluorophosphate, lithium tetrafluoroborate, etc. dissolved in a solvent that comprises a mixture of organic carbonates such as ethylene carbonate, diethyl carbonate, etc. Depending upon the material choice, the cell voltage, capacity, performance, and safety can change dramatically. The most common cell design formats of Li-ion cells include cylindrical, prismatic, and pouch. In this section, the working mechanism of Li-ion cells has been discussed along with an overview of each cell component (negative electrode, positive electrode, electrolyte, and separator). Later part of this chapter would add more information on each of them including the modern trend.

Li-ion Cell Mechanism

A typical Li-ion cell consists of a positive electrode composed of a thin layer of powdered metal oxide (e.g., $LiCoO_2$) coated on aluminum foil and a negative electrode formed from a thin layer of powdered graphite, mounted on a copper foil. The two electrodes are separated by a porous polyolefin film called as separator soaked typically in a electrolyte made of LiPF6 salt dissolved in a mixture of organic solvents such as ethylene carbonate (EC), ethyl methyl carbonate (EMC), or diethyl carbonate (DEC).

During cell operation, all the three functional components participate in the electrochemical reaction. Both the negative and positive electrodes are materials into which, and from which, lithium can migrate. During insertion (or intercalation), lithium moves into the electrode and during extraction (or deintercalation), lithium moves back out. During discharge, the lithium ions are deintercalated from the negative electrode moved through the electrolyte and intercalated into the positive electrode. The reverse happens during charging in which lithium ions deintercalate from positive electrode and gets intercalated into the negative electrode. Figure 6 shows the schematic representation of the operation of a lithium-ion cell during discharge process. Useful work can only be extracted if electrons flow through a closed external circuit.

The positive electrode half-cell reaction (with charging being forward) can be represented as:

$$LiCoO_2 \Leftrightarrow Li_{1-x}CoO_2 + xLi^+ + xe^-$$

The negative electrode half-reaction (with charging being forward) is:

$$xLi^+ + xe^- + 6C \Leftrightarrow Li_xC_6$$

where x refer to moles of lithium. The overall cell reaction can thus be represented as:

$$LiCoO_2 + 6C \Leftrightarrow Li_{1-x}CoO_2 + Li_xC_6$$

where the forward reaction corresponds to charging and the reverse reaction occurs during discharge.

Negative Electrode Material (Anode)

The basic requirements for a negative electrode material to be used in lithium-ion cell are that the material should have minimal volume expansion and stress associated with it during charge/discharge process, higher electronic conductivity, lower irreversible capacity loss during first charging or intercalation process, stable under wide operating temperature window in a highly reducing environment, and lower specific surface area (typically <2 m^2/g) for optimal performance and safety.

There are many types of carbonaceous materials being used as negative electrode active material for Li-ion cells. Carbon materials can be broadly classified into amorphous and crystalline. Crystalline or graphitic carbon is a typical layered compound that consists of hexagonal grapheme sheets. Although graphite exists in nature, it can be synthesized artificially by treating a pyrolyzed carbon at high temperatures around 3,000°C.

Amorphous kind carbon includes materials that are heat-treated at lower temperatures of around 1,100–1,300°C and has low crystallinity. They include

Lithium-Ion Battery Systems and Technology. Figure 6
Schematic representation of Li-ion cell operating mechanism

"soft carbons" (graphitizable carbons) and "hard carbons" (non-graphitizable carbons). In soft carbons, small crystallites are stacked nearly in the same direction, and thereby, subtle diffusion induced upon heating results in graphitization. In contrast, the crystallites of hard carbons do not have such distinct orientation and, hence, are difficult to develop even when heat-treated at high temperatures >3,000°C. Soft carbon material is mostly being used to surface treat the graphite material. The practical materials most widely used in commercial cells include hard carbon, natural graphite, synthetic graphite, and amorphous carbon coated graphite.

Lithium-Ion Battery Systems and Technology. Figure 7 Typical charge/discharge characteristics of graphitic carbon material

Solid Electrolyte Interface (SEI)

During the first charging after cell assembly, a protective film has been formed on the surface of the negative electrode through reductive decomposition of the electrolytic solution [14, 15]. The passivation film often called as solid electrolyte interface (SEI) acts as an interface between the electrode surface and the electrolyte solution and has the properties of a solid electrolyte with high electronic resistivity. Other favorable properties of the SEI include good mechanical stability/flexibility and good adhesion to the anode. In general, SEI film consists of insoluble and partially soluble reduction products of the electrolyte components. Formation of SEI film suppresses further solvent decomposition and plays a beneficial role in improving the safety and cyclability of lithium ion cells. The SEI formation on negative electrodes thus is a prerequisite for their stable charging and discharging; however, it is the primary cause for the irreversible capacity loss during the first charge through consumption of a considerable amount of lithium. The electrolyte often has additives to enhance SEI formation.

Figure 7 shows a typical charge/discharge characteristic of graphitic carbon material. The solid line represents the intercalation or charging, and the dotted line shows the deintercalation or discharging. During first intercalation (charging), the potential drops rapidly after subtle retardation at ~0.8 V (vs. Li^+/Li). Most of the Li intercalation and deintercalation takes place at potentials <0.25 V (vs. Li^+/Li), accompanied by three potential plateaus. Charge consumed upon first charging is not fully recovered upon discharging and the capacity that cannot be recovered is called irreversible capacity which is observed for any carbonaceous material due to the formation of a passive film over the surface of electrode referred as solid electrolyte interface (SEI). At the second and subsequent cycles, graphite shows good reversibility and the reversible specific capacity ranges from 300 to 370 mAh/g. Table 1 shows the properties of a few commonly used negative electrode materials of Li-ion cells. Graphitic carbons can insert lithium up to a stoichiometry of LiC_6 corresponding to 372 mAh/g.

Positive Electrode Material (Cathode)

In general, positive electrodes in commercially available Li-ion cells utilize a lithiated metal oxide as the active material. Most of the research and commercialization efforts has centered on two classes of materials. The first group includes materials with layered structure that enables two-dimensional diffusion of lithium ions or a spinel structure which enables three-dimensional diffusion as the transition-metal ions are ordered in all layers. Examples include $LiCoO_2$, $LiNiO_2$, $LiNi_{1-y}Co_yO_2$, etc. for layered compounds and $LiMn_2O_4$ for spinel type compound. The second group includes materials with more open structures like vanadium oxide, transition-metal phosphates namely olivine ($LiFePO_4$). The first group, because of their more compact lattices, will have an inherent

Lithium-Ion Battery Systems and Technology. Table 1
for lithium-ion cell

Anode type	First charge capacity (mAh/g)	Irreversible capacity loss	Practical capacity (mAh/g)
Hard carbon	250	25–30%	180–190
Natural graphite	370	16–18%	300–320
Surface treated natural graphite	370	7–9%	340
MCMB graphite	350	10–12%	310–320
Massive artificial graphite (MAG)	360	5–8%	330–340
Mesophase carbon fiber (MCF)	350	10–12%	310

advantage in energy stored per unit of volume, but the second group compound like $LiFePO_4$ is cheaper [16]. Figure 8 shows the charge/discharge characteristics of $LiCoO_2$ material. The theoretical specific capacity of the $LiCoO_2$ cell is relatively low at around 130 mAh/g because only around 0.5 Li/Co can be reversibly cycled without causing cell capacity loss due to changes in the $LiCoO_2$ structure associated with the phase changes that cause low reaction rates and also poor stability of the electrode at low lithium contents. Table 2 shows the properties of a few commonly used positive electrode materials of Li-ion cells.

The ideal requirements for a positive electrode active material used in lithium-ion cell are that the material needs to contain a readily reducible/oxidizable atom, like a transition metal; should react with lithium in a reversible manner without changing the host structure; be a good electronic conductor; be able to react with lithium very rapidly to provide higher power density; should react with lithium with a high free energy of reaction to obtain high voltage, high capacity, and hence high-energy storage; and be stable under

[a]Charge cutoff voltage is ~3.65 V

Lithium-Ion Battery Systems and Technology. Figure 9 Schematic showing charge/discharge characteristic of Li-ion cell electrode and state of charge operating window after SEI formation

wide voltage and temperature window. There are several physical properties that determine the quality of positive electrode active material and also influence the battery characteristics. They include particle size, shape, distribution of particle size, water content, tap density, specific surface area, crystallinity, impurity level, and so on.

Cell Balance

Lithium-ion cells operate by cycling lithium ions between two insertion electrode hosts having different insertion energies. Figure 9 shows the schematic of charge discharge characteristics of Li-ion cell electrodes (e.g., $LiCoO_2$ as positive and graphite as negative electrode) [17]. After assembling and filling with electrolyte, the cell will be in a completely discharged state where all the lithium ions are present in the positive electrode. During initial charging, some portion of the lithium ions goes into the irreversible SEI film formation reaction and rest of the lithium ions gets intercalated into the negative electrode. The negative to positive electrode capacity ratio is very critical in determining the cell performance and safety with continuous cycling. Smaller capacity ratios would present safety hazard as the negative electrode can get overcharged as more lithium ions are available for intercalation than is desirable. Higher capacity ratios may prevent optimal utilization of the negative electrode. The typical negative to positive electrode capacity ratio used by most cell manufacturers is around 1.15. The first charge capacity of negative electrode (Li-ion intercalation) needs to be at least 15% greater than the first charge capacity of the positive electrode (Li-ion deintercalation) to accommodate the SEI formation.

Electrolyte

Electrolyte is one of the critical components for any electrochemical device, and the basic function is to serve as the medium for the transfer of charges, which are in the form of solvated ions, between a pair of electrodes. The role of liquid electrolytes in lithium-ion cells is to act as an ionic conductor to transport solvated lithium ions back and forth between positive and negative electrodes as the cells are charged and discharged. Since the electrodes in lithium-ion cells are the porous composite electrodes, consisting of an active material, a conductive material and a polymer binder, the liquid electrolyte must seep into the porous electrodes and transfer lithium ions smoothly at the interfaces between the liquid and solid phases. The minimal requirements of the electrolyte used in Li-ion cells include good ionic conductivity and electronic insulator property, stability over a wide electrochemical voltage window and operating temperature. Most commonly used salt materials for the electrolyte include $LiPF_6$, $LiBF_4$, and the most common solvents are carbonate based, namely, EC, DMC, DEC, EMC, and PC.

An ideal electrolyte solvent for Li-ion cells shall meet the following minimal criteria, namely, high dielectric constant, to be able to dissolve salts of sufficient concentration, lower viscosity for facile ion transport, inert to all cell components, especially the charged surfaces of the electrodes, lower melting point, and higher boiling point to remain liquid in a wide temperature range.

An ideal electrolyte solute in lithium-ion cells completely dissolves and dissociate, in the nonaqueous media, and the solvated ions should be able to move in the media with high mobility, should be stable against oxidative decomposition at the positive electrode, should be inert to electrolyte solvents and other cell components, and should be nontoxic and remain stable against thermally induced reactions with electrolyte solvents and other cell components. LiPF6 is one of the most commonly used salts on commercial Li-ion cells. The success of LiPF6 was not achieved by any single outstanding property but, rather, by the combination of well-balanced properties, namely, conductivity, ionic mobility, dissociation constant, thermal stability, and electrochemical/chemical stability.

Electrolyte Additives Electrolyte additives are compounds that add extra functions to the liquid electrolytes in addition to the fundamental function as an ionic conductor. Examples of role-assigned electrolytes include anode passivation film-forming agents, cathode protection agents, overcharge protection agents, wetting agents, flame retardant agents, and so on. It should be noted that small amount of the electrolyte additives dramatically improves the performances of lithium-ion cells. Since the influence of electrolyte additives depends not only on the electrode materials but also on cell designs, the research and development of the additives is quite challenging.

Separators

A separator is a porous membrane physically placed between electrodes of opposite polarity, permeable to ionic flow but preventing electric contact between the electrodes. As batteries have become much sophisticated, separator function also has become more demanding and complex. The main function of separator in Li-ion cell is to keep the positive and negative electrodes apart to prevent electrical short circuits and, at the same time, allow rapid transport of ionic charge carriers that are needed to complete the circuit during the passage of current in an electrochemical cell. They should be very good electronic insulators and have the capability of conducting ions by soaking electrolyte. Li-ion battery separators can be produced through dry and wet processes. Figure 10 presents the micrographs of separator membrane produced through dry and wet process methods.

A wide variety of properties are required for separators used in Li-ion cells [18]. They include: electronic insulator, minimal electrolyte (ionic) resistance, sufficient mechanical and dimensional stability and physical strength to allow easy handling, chemical stability to degradation by electrolyte, impurities, and electrode reactants and products, readily wetted by electrolyte

Lithium-Ion Battery Systems and Technology. Figure 10
SEM images of separator membrane produced through (**a**) dry and (**b**) wet process methods

and effective in preventing migration of particles or soluble species between the two electrodes. In order to achieve good performance of Li-ion cells, the separators should have higher ionic conductivity with electrolyte, low shrinkage, and uniform pore structure. Cells with high-resistance separators will perform poorly during high rate discharge and also will increase the cell-charging time.

Microporous polyolefin membranes in current use are thin (<30 um) and are made of polyethylene (PE), polypropylene (PP), or laminates of polyethylene and polypropylene. They are made up of polyolefin materials because they provide excellent mechanical properties, chemical stability, and acceptable cost. They have been found to be compatible with the cell chemistry and can be cycled for several hundred cycles without significant degradation in chemical or physical properties.

Manufacturing Process

The basic principles and processes of cell design and fabrication are well known and quite similar among cell manufacturers. The International Electrotechnical Commission (IEC) has established a common nomenclature for describing the various cell sizes and chemistry. For example, the most common cylindrical Li-ion cell ICR18650 translates into: I is for Li-ion technology, C for cobalt-based cathode, R is for a round cell, 18 is for the cell diameter in millimeters, and 650 is for the cell height in tenths of a millimeter.

The overall manufacturing process for the Li-ion cell can be divided into the five major processes:

1. Mixing, kneading, coating, pressing, and slitting processes of the positive electrode and negative electrode materials
2. Winding process of the positive electrode, negative electrode, and separator
3. Insertion of the wound cell core and electrolyte injection into the battery case
4. Cell closing or sealing process
5. Formation, aging, and cell selection

Electrode Fabrication and Winding Process

Figure 11 shows an outline of the initial process of Li-ion cell manufacturing that includes electrode preparation to winding [19]. In this process, the active materials are coated onto metal foils and calendered for thickness. The positive electrode material consists of active material, such as $LiCoO_2$, $LiNiO_2$, or $LiMn_2O_4$; a carbon-conductive additive like acetylene black; and a binder material namely polyvinylidene difluoride (PVdF). The active material and conductive agent are first dried and are then fed into a ball mill or other mixer along with the previously prepared binder solution (e.g., PVDF dissolved in *N* -methyl pyrrolidone), and then thoroughly stirred. The ball mill contains ceramic balls, e.g., glass, zirconia, about 2–3 mm in diameter, to assist in mixing and the mixing condition can strongly influence the performance of the cell.

The process for the negative electrode follows essentially similar to that of the positive electrode but with different materials. Carbon or graphite is used for the negative electrode-active material. PVDF, carboxymethylcellulose (CMC), or styrene butadiene rubber (SBR) is generally used for the binder that is usually dissolved in solutions like NMP depending on the type of binder.

A better result in mixing may be obtained by first kneading the materials into a stiff paste and then adjusting the viscosity by adding the solvent so that it can be applied easily in the coating process. The electrode slurries (viscosity from 10,000 to 20,000 cps) are uniformly coated onto both sides of the current collector (aluminum foil for the positive and copper foil for the negative) of 10–20 μm thickness. Proper mixing techniques are very critical to obtain uniform distribution of the components of the active mass during the coating operation.

Coating operations can use a slot die, reverse roll coating, or doctor blade coating equipment. Close control of coating thickness is essential to ensure that all the parts fit into the can during final assembly. The coating thickness for different cell designs can vary from 50 to 300 μm, depending on the cell design. The coated material is dried in a continuous process. The coating solvent is collected to prevent emission of toxic vapors. Next, the dried electrodes undergo calendaring process where it is compressed with a roller press machine to provide accurate thickness control of the electrode thickness and to increase the density of the electrode mass. After

Lithium-Ion Battery Systems and Technology. Figure 11
Schematic of battery electrode fabrication process

calendaring, the master roll is slit to the width specified for cell construction and wound onto a roll for the winding operations.

18650 Cell Fabrication Process

Figure 12 presents the schematic of the assembly of cylindrical cells [19]. The reels of the slit anode, cathode, and separator stock are mounted on the winding machine. The strips have been sized for length, width, and thickness that match the cell design. Once the foils are threaded into the machine, the machine starts and continues to operate automatically until the reels are used up. An aluminum tab is affixed to the bare part of the aluminum foil positive electrode by ultrasonic welding before winding, and similarly, a nickel or copper tab is affixed to the copper negative electrode collector by ultrasonic welding.

The winding machine then combines the two electrodes and separator strip on a mandrel (also referred as pin) and winds the combination in jellyroll fashion into a tight bobbin or cell core. Cylindrical cells are wound on a round mandrel while the prismatic cells use a flat paddle. Winding requires constant tension on the coil as it is formed and grows to the final size. Any irregularity leads to a gap between the separator and electrode, resulting in a nonuniform current distribution that can lead to a malfunction or shortened cycle life. The wound coil is checked for internal shorts before being inserted into the can with a hi-pot or impedance tester. In the last step, the cell core is taped to keep it tightly wound before inserting it into the cell case. It is important that the active material neither peels or sloughs off of the active material nor the separator twists during the winding process. Early rejection of potential cell faults is economical and prevents investing more work on bad/faulty cells.

Following insertion into the cell case, a tubular mandrel with a serration may be inserted in the winding core. The function of this mandrel is to improve the

Lithium-Ion Battery Systems and Technology. Figure 12
Schematic of 18650 cell fabrication process

integrity of the cell core and for safety of the battery. When the internal pressure rises, gas has free passage through the hollow center of the mandrel and is released through the vent. When the cell is crushed, the mandrel causes both electrodes to short-circuit and instantaneously discharge. Any moisture contamination of the cell has a deleterious effect on its operation. Therefore, all cell assembly operations are usually carried out in a dry room or dry box. Alternatively, the cell then may be put in a heated vacuum oven for certain durations in order to extract residual water from the cell core before electrolyte filling. In the next process, the cell is filled with the electrolyte using a vacuum injection apparatus.

After filling, the cell cap, also called the header, is welded to the aluminum tab and the cell is finally sealed by crimping the header to the can. The header contains the polymer spacer, vent, PTC, and CID safety devices designed to activate and prevent dangerous temperatures and pressures from developing internal to the cell. After sealing, the cells are completely washed with isopropyl alcohol or acetone in order to remove any adhering electrolyte. An electrolyte leakage test is done using a smell sensor apparatus in order to confirm a good seal. Finally, the cell is subjected to an aging process to select out cells with microshorts and to categorize cells by capacity for assembly into battery packs. The temperature, length of storage, and cell checking methodology vary. This process is designed to identify cells with internal cell faults and microshorts that are not found during cell fabrication.

Large Format Li-Ion Cell Manufacturing Process: Flat Plate Pouch Configuration

Li-ion polymer and flat plate cells are produced in small sizes for cellular phones (about 0.5 Ah and higher) and large sizes (up to 200 Ah) for energy storage and motive power applications. A common characteristic is that the polymer separator holds the electrolyte and forms a physical barrier between the anode and cathode to prevent internal shorting. Most polymer cells are flat plate (prismatic) construction.

Lithium-Ion Battery Systems and Technology. Figure 13
Schematic of pouch cell fabrication process

There is no one general cell fabrication process for polymer, flat or pouch, cells as there is for the liquid electrolyte cylindrical and prismatic cells. Each manufacturer has a slightly different process flow. Cell designs are essentially laminated constructions produced by several different fabrication processes. A typical example was shown in Fig. 13 [19]. Cell assembly follows the general outline as that for cylindrical cells. The cell assembly could be either a wound design or a stack design. Wound design follows closely to that of cylindrical cell except that the mandrel would be a thin flat plate depending upon the width requirement. In stack design, positive and negative electrodes along with separator are stacked together to give the desired cell capacity. Alternatively, a Z-fold construction may also be used with the electrodes bonded to the separator [20]. The stacks then are bonded together using ultrasonic or heat to ensure uniform bonding and dimensional control.

The cell case is formed from an aluminum-polymer laminated film. The film is fusion bonded, the electrode stack is inserted, and the exterior case is fused by a heat or an ultrasonic sealing apparatus. The assembly then is checked for internal shorts, the moisture is removed by heating in a vacuum dryer, the electrolyte (polymer or conventional electrolyte depending upon the cell kind) is then injected, and the cell is vacuum-sealed in a two-chamber configuration. After formation, any gas formed is removed by a vacuum, the cell resealed, and the gas chamber discarded. Finally, the cell is subjected to top sizing, both side bending, leakage tested with an odor sensor, cleaning and drying, inspection of any coil winding misalignment

using an X-ray apparatus, lot number printing, storage, charging and discharging, and then final inspection.

Formation and Aging

Once the cell assembly process is complete, the final step in the overall production process shifts to the formation and aging of the cells. This applies to cylindrical, prismatic, flat plate, and polymer cell constructions. Li-ion cells are assembled in the discharged condition and must be activated by charging. The first charge is called "formation," which activates the active materials in the cells and establishes their ability to function. The first charge typically starts at a lower current to properly form the protective solid electrolyte interface (SEI) layer on the graphite/carbon anode and then increases to the normal current at about 30% into the charge period.

The cell voltage is measured after the first charge and stored (aged) for a set time period. The storage time and temperature vary from one manufacturer to another. The voltage and capacity measurements are stored for use in the cell-selection/-matching process. These will be used later to sort cells out with internal microshorts or other manufacturing defects. Differences in voltage at the start and end of the storage period can be used to identify problem cells with low voltage and low capacity. Cells with low voltage result from "soft" or "micro" internal shorts and are discarded. The exact first charge regimen and cell-selection procedure may vary with manufacturer. Some manufacturers give the cell one or two cycles after formation to check the capacity for cell matching in assembly of battery packs. Others use the voltage measurement after first charge.

In order to keep up with the market demands, tough quality, performance, and safety requirements, in the cell fabrication methods and process control techniques, are followed. Optical and X-ray systems are currently being used to continuously monitor critical processes like winding, and ensure precise placement of components. The electrolyte-filling process is completely automated by using precision pump combined with advanced multistep vacuum/pressure cycles to ensure that the electrolyte permeates and completely fills the porosity in the separator and electrode structures. The internal construction of every cell produced is inspected by X-ray for proper top cap installation, misalignment of the winding from processing, the improper bending of the tabs, and so forth, which potentially could cause an internal short circuit or cell malfunction.

Safety

Lithium-ion batteries have been commercially available for over 2 decades and currently represent state-of-the-art power source for all modern consumer electronic devices. Due to its advanced chemistry, Li-ion cells exhibit superior performance characteristics over most other rechargeable battery systems. The lithium-ion technology offers a high energy and power density, long life, and reliability that makes it attractive for electric drive vehicle (EDV), military, and aerospace fields, and large format Li-ion cells and battery packs are currently under development for such applications.

Like any other energy storage devices, one of the concerns about the Li-ion technology is the safety associated with the system and is the primary focus for cell/pack manufacturers apart from cost and durability. Li-ion cells can undergo thermal runaway if subjected to unreasonable conditions for which they are not designed as it involves a combination of highly energetic materials with flammable electrolyte solutions.

With several billion Li-ion cells being used to power cell phones, laptops, and other consumer electronics, there are bound to be concerns over field incidents [21–23]. Battery failures that vent with fire are taken very seriously and manufacturers choose a conservative approach by adopting safety recalls. Considering the number of lithium-ion batteries used in the market, this energy storage system has caused little harm in terms of damage and personal injury.

Li-ion cells have had an excellent safety record in the field with very few documented safety events in over one billion cells in the market place. Safety is continuously improving since production rates are increasing. This excellent safety record has come about due to care on the part of manufacturers and due to regulatory standards like IEEE, IEC, and UL governing the safety

of cells. Cell manufacturers are not only trying packing more energy into the pack but also attempting to make it safer. However, there is still room for further improvement in safety as Li-ion system moves into several new arenas like electric cars and trucks, stationary energy storage, military and satellite applications that mostly utilize larger format batteries.

System Level Safety

In general, ensuring a safe product begins at cell level and ends with the user. The IEEE 1625 standard for laptops and the IEEE 1725 standard for mobile phones have recently focused on conveying the concept that Li-ion battery pack safety is a function of the entirety of the cell, pack, system design, and manufacture [24, 25]. A system level approach thus becomes very essential in addressing the safety of Li-ion batteries. System level safety includes the combination of cell, battery pack, host device, power supply, or adapter, end user/environment, and each of these aspects has a role to play in ensuring pack safety. Figure 14 presents the schematic of the system approach to Li-ion design and use. The level of assurance for protection and safety on system level depends on the implementation by the manufacturer/supplier and also on the actions of the end user. This part of system level safety is about understanding the intended use of a product, and mitigating reasonable and foreseeable misuse that may occur. IEEE P1625, the Standard for Rechargeable Batteries for Portable Computing, was the first standard to encompass all levels of the battery manufacturing process and include the customer experience.

Cell Level Safety

The safety of lithium-ion batteries is an essential requirement for commercial use. Cell manufacturers continue to work toward designing safer cells, through modifications of cell components and through improvements in manufacturing practices that ultimately resulted in cells exhibiting excellent safety record in the field. On cell level, thermal runaway failures can occur for a number of reasons, including poor cell design (electrochemical or mechanical), cell manufacturing flaws, external abuse of cells, etc.

The cell level safety can be broadly classified into three categories shown in Fig. 15. The first one

Lithium-Ion Battery Systems and Technology. Figure 14
System approach to Li-ion design and use (IEEE)

Lithium-Ion Battery Systems and Technology. Figure 15
A schematic flowchart that represents the cell level safety in Li-ion cells for consumer electronics applications

represents safety that depends upon cell design aspects, namely, materials and process conditions. Cell manufacturers around the world are now adapting more sophisticated processes to produce Li-ion cells. The process is highly automated and more efficient with advanced quality control checks based on optical and X-ray inspection techniques to check on several key safety-related factors such as electrode alignment, presence of metal contaminants, presence of burrs in electrode edges, insulation of aluminum current collector next to electrode coating that faces the negative electrode, and so on. Moreover, using advanced electrodes with surface treated and core-shell type materials, very safe electrode capacity ratio, through implementing several cell level safety features, etc., greatly improves the cell level safety. The category can also be referred as bulk safety as almost 99.999% of the cells produced currently for consumer electronics applications by well-experienced cell manufacturers fall into this category. Bulk safety is not a concern with current advanced Li-ion technology as cells are being made with optimized process conditions, with robust design and advanced material choice that when operated under recommended user conditions is much safer and will not result in thermal runaway situations during its operation period.

The second category addressing cell level safety concern is the abuse tolerance. The term "abuse" refers to using of product in a way that is not intended by the supplier but which may result from unreasonable human behavior or unreasonably extreme environmental conditions [24]. Cell designs that are

tolerant to abuse conditions without venting or self-destruction are imperative. Abuse tolerance tests for consumer electronics cells are defined by International Electrotechnical Committee (IEC), Underwriters Laboratories Inc. (UL), and Japan Storage Battery Association (JSBA). The tests are typically classified as thermal, electrical, and mechanical abuse tests. Thermal abuse tests include high-temperature ramp also referred as hot-oven test and temperature cycling test. Characterization test methods, namely, ARC and DSC, are widely used to study the thermal properties of the cell components such as self-heat rate, onset runaway temperature, and so on that are directly linked to the thermal stability of the materials, and these test methods provide insight on thermal abuse tolerance response of Li-ion cells. Overcharge and external short circuit tests are categorized as electrical abuse tests and the most common mechanical abuse tests include crush, nail penetration, crush, impact and vibration tests. For more details regarding each test condition, UL document 1642 could be referred [26]. Cell manufacturers in general adopt a scaling method in quantifying the abuse response of Li-ion cells. The response may be ranging from least severe ones, namely, no change, vent with electrolyte leakage, to the most severe ones like smoke with fire and explosion. For abuse tolerance tests, the criterion for the cell to pass is no fire and no explosion.

The third category is the PPB or parts per billion level safety that refers to the field incidents of Li-ion cells that were subjected to normal recommended operating conditions. Field failures typically represent unprovoked battery explosions, and according to industry experts, such events are rare and it is estimated that one in ten million lithium-ion batteries fail that way [27]. Stringent quality control measures and new safety evaluation methods are being recommended that would help in controlling PPB level. Battery Association of Japan has developed a test methodology to analyze internal short occurring in a Li-ion cell and to characterize the failure associated with it [24]. With this test method, the field incident caused by internal short circuit can be simulated practically [28]. With the increase in the energy of lithium-ion batteries, more advances in safety technology are also necessary to reduce the field incidents still further and gain more consideration from EDV, satellite, and other specialty applications.

More Details on Cell Components and Modern Trend

Negative Electrode Material

Hard Carbon One of the typical examples for hard-carbon materials is the thermal decomposition product of polyfurfuryl alcohol resin (PFA). Hard-carbon materials can offer higher capacity beyond the theoretical limit of LiC_6 at lower potentials but have not achieved broad acceptance because of their higher irreversible capacity and sloping discharge voltages [29]. They are highly sensitive to moisture and are difficult to process; however, the material is practically usable and able to offer around 200 mAh/g capacity. Significant research work has been carried out on hard carbon with the purpose of overcoming the drawbacks through surface modifications and pretreatments. But graphitic carbon is still considered the best choice in practical batteries because of its higher performances.

Graphite Intercalation Compounds (GIC) Theoretically, graphitic carbons can insert lithium up to a stoichiometry of LiC_6 corresponding to 372 mAh/g. The process is called intercalation and Li-ions occupy sites between graphene planes. Morphology of graphitic materials has a strong impact on electrochemical behavior and strongly influences critical stages in the precipitation of the surface films and their passivation properties. In general, graphite particles with some degree of disorder show high reversibility and stability in Li insertion process and are less dependent on solution composition when compared to highly ordered materials.

Graphite intercalation compounds (GIC) have a significant feature called the staging phenomenon, which is characterized by a periodic sequence of intercalant layers (lithium ions) between graphite layers. The nth-stage compound consists of intercalant layers arranged between every n graphite layers. The first-stage lithium graphite intercalation compound has the stoichiometry of LiC_6 with the specific capacity of 372 mAh/g, a theoretical saturated value of lithium

storage for graphite under normal pressure. The staging phenomenon can be easily monitored and controlled by the electrochemical reactions of carbons in Li^+-containing electrolytes, for instance, conducting galvanostatic (constant current) charge/discharge [30] and slow cyclic voltammetric(CV) [31, 32] tests, and analyzing the differential capacity (dQ/dV vs V, where Q is capacity and V is voltage) has proven to be a particularly useful electrochemical method. In conjunction with the electrochemical techniques, some physical methods have been applied to shed light on the stage occurrence and transitions during lithium intercalation into and deintercalation from graphite host. These methods include in situ XRD [30, 33], ex situ XRD [34], in situ laser Raman spectra [35], and STM [36].

Natural Graphite Natural graphite is chosen for lithium-ion battery anode materials mainly because of its low cost, low and flat potential profile, high Coulombic efficiency in proper electrolytes, and relatively high reversible capacity (330–350 mAh/g). On the other hand, it has two main shortcomings, namely, low rate capacity and incompatibility with PC-based electrolytes.

The low rate capacity is primarily due to its high anisotropy causing unfavorable orientation of particles that leads to sluggish of Li^+ intercalation and inadequate electronic contact between graphite particles and copper substrate [37, 38]. To overcome this issue, mechanical millings have been applied to pulverize the natural graphite flakes into small pieces [39], through which the preferred orientation of crystallites within each natural graphite flake particle can be distorted to some extent by separated graphite fragments. One other limitation of natural graphite is its incompatibility with PC-based electrolytes. Studies have been carried out to overcome this through modifying the electrolytes with additives and also modifying the graphite by coating amorphous carbon layers through thermal vapor decomposition technique [40–42].

Synthetic Graphite Synthetic graphite has many properties that are similar to those of natural graphite. Besides, it has many unique merits such as high purity, variety of structures suitable for smooth Li^+ intercalation and diffusion, and so forth. Nevertheless, it is more expensive because of the high-temperature treatment (>2,800°C) on soft carbon precursors, and its reversible capacity is a little smaller than natural graphite.

Graphitized MCMB, mesophase-pitch-based carbon fiber (MCF), and vapor-grown carbon fiber (VGCF) are the representatives of benchmark synthetic graphite anode materials for Li-ion batteries in the market today. Graphitized MCMB has many advantages, namely, high packing density that guarantees high-energy density, and small surface area that decreases the irreversible capacity corresponding to electrolyte decomposition; most surfaces of MCMB spheres are composed of edge-plane surfaces, thus facilitating Li^+ intercalation and higher rate capability, ease of spreading onto copper foil.

Although amorphous carbon and spherical mesophase base graphite have been used mainly as anode materials in Li-ion cells, artificial graphitic carbon also called as massive artificial graphite (MAG) with lower voltage and the higher energy density is being used mainly to fulfill the difficult requirement for mobile equipment in recent years. MAG has been developed for the mass production of unique graphite for the purpose of battery application [43].

The MAG particles consist of spherical aggregation of fine, flat crystals. It has an average diameter of 20–30 μm and an aspect ratio of about one. MAG particles have a pseudo-isotropic texture where primary flat particles are randomly aggregated that also aids in tolerating expansion and shrinkage during charge/discharge operation. The discharge capacity of MAG exhibits a value of 362 mAh/g, which is very close to the theoretical one (372 mAh/g) of graphite. Graphite with a high crystallinity, which has a smaller interlayer spacing in the crystal, has relatively higher discharge capacity. This could be attributed to the fact that the graphite with the higher crystallinity is mainly composed of regular stacking structure, which is suitable for the formation of Li-GIC. Studies also have shown that the movement of Li^+ ions in MAG occurs in the vertical direction to the collector during the charge/discharge and Li^+ insertion into graphite occurring at the edge of graphite crystal, thereby having an easier lithium transfer and hence better high rate performance compared to flaky natural graphite [43].

Lithium Titanate Anode Lithium titanate ($Li_4Ti_5O_{12}$, referred to as LTO) is another promising anode material for certain niche applications that require high C rates, fast charging capability. Some of the challenges for the LTO-based cells include lower voltage (2.5 V vs. LCO and 1.9 V vs. LFP), lower capacity, and excellent high-temperature stability. It has superior high rate performance with very long cycle life. It is being developed for automotive and energy storage applications.

Silicon-Based Anode Existing lithium-ion batteries using graphite anodes have inherent limited Ah capacity. Silicon-based anodes theoretically offer as much as a tenfold capacity improvement over graphite. Silicon, when converted to the compound $Li_{21}Si_5$ by reaction with lithium in an electrochemical cell, has a maximum capacity of 4,200 mAh/g [44]. Due to its relatively low cost, low toxicity, and higher theoretical capacity, silicon is one of the promising candidates to replace graphite anode in Li-ion systems.

However, implementation of Si as an anode material is greatly hampered by several factors such as large volume change, low intrinsic electrical conductivity, and poor cyclability. The loss of capacity on repeated cycling is attributed to mechanical fragmentation and electrical isolation of silicon species due to the volumetric expansion and contraction associated with lithium insertion and extraction [45]. Many experimental techniques were investigated to analyze the cycling behavior and investigate mechanical degradation upon cycling [46, 47]. The reaction of silicon with lithium produces various alloy-type compounds (LixSiy) and causes enormous volume changes of up to 300% during the charge/discharge process, and this, together with the low electrical conductivity of silicon, obstructs the commercial use of silicon as a negative electrode material [48].

There are several approaches used to date for investigating silicon-based anodes. The thin-film approach involves deposition of an active silicon layer as a continuous media on a specially roughened metal or carbon current collector using ion sputtering [49, 50] or vapor deposition techniques [51, 52]. The film formation method, which results in strong adhesion between the current collector and very thin silicon layer, leads to the formation of a stable, self-organized columnar structure during the first volumetric expansion. This structure remains stable over cycles and aids in providing cycling stability of the films. Despite such attractive features of thin silicon film electrodes, they are yet to be commercialized. The thin silicon film electrodes are an order of magnitude thinner than cathodes, which might cause technological problems [53] and does not seem to be easily scalable. Moreover, solid electrolyte interface (SEI) film formation mechanism has yet to be studied in detail [54] and might highlight potential complications for real LIB employing such electrodes, especially during long-term cycling.

The approach is the composite electrode approach that relies on the use of silicon in the form of tiny silicon "cores," uniformly distributed within an electrochemically active or inactive buffering media, which prevents silicon-silicon interaction and the formation of large clusters. The core-shell structured anode materials comprising Si/SiO_2 blended with graphite material are good examples for the composite concept and have been gaining much attention primarily due to its ability to deliver higher capacity with continuous cycling, longer and stable cycling performance with much lower volume change than other silicon-based systems under study. Mixtures of silicon and different blends of graphite were studied and it was found that graphite is important in improving cycling performance [55, 56]. To suppress the volume effects of silicon upon cycling, techniques such as pyrolyzed PVC reactions and high-energy mechanical milling (HEMM) were adopted to disperse ultrafine silicon into a feasible carbonaceous matrix that shows promising results on improving the coulombic efficiency after the first cycle [57]. Further optimization of Si-composite based anodes could lead to practical lithium-ion batteries with high-energy density.

Positive Electrode Material

$LiCoO_2$ Lithium cobalt oxide (LCO) is the primarily used positive electrode–active material of Li-ion rechargeable cells. The simplicity involved in manufacturing and the balanced cell characteristics, namely, cycle performance, rate capability, high and low-temperature performance, safety, and so on, are some of the reasons why LCO is a leading player among

positive electrode–active materials. However, as the Li-ion market is driven by cost reduction both in consumer electronics and in the vehicle and stationary storage segment combined with the present higher market price of cobalt, the application of LCO material is decreasing and focus now shifts more toward nickel, manganese, and iron type materials and cobalt-doped layered mixed oxide materials.

$LiCoO_2$ is obtained using a cobalt compound and a lithium compound as the raw materials and heating. Today cobalt oxide (Co_3O_4) is used as the cobalt compound and lithium carbonate (Li_2CO_3) as the lithium compound due to the stability of their quality and supply, the easiness of handling. The reaction scheme for the $LiCoO_2$ can be indicated as:

$$2Co_3O_4 + 3Li_2CO_3 + 1/2O_2 \rightarrow 6LiCoO_2 + 3CO_2$$

Goodenough recognized that $LiCoO_2$ had a structure similar to the layered structures of the dichalcogenides and showed that the lithium could be reversibly removed electrochemically, thus making it a viable cathode material [58].

$LiNiO_2$ Lithium nickel oxide is isostructural with lithium cobalt oxide and has higher specific capacity. However, it is much more susceptible to thermal runaway and has not been used in commercially lithium-ion cells.

$LiMn_2O_4$ (Spinel) James Hunter of Eveready Battery Co. was the first to patent spinel cathode material. The application of material to Li-ion system has been developed by J. M. Tarascon [59] and extensively studied by M. Thackeray [60]. Generally, lithium spinel oxides suitable for the cathode are limited to those with a normal spinel in which the lithium ions occupy the tetrahedral (8a) sites and the transition-metal ions reside at the octahedral (16d) sites. Currently, spinel is the center of much interest as the cathode material for large format lithium-ion cell for hybrid electric vehicle applications where high power, safety, and low cost are the strongly required features.

Olivine Compound ($LiFePO_4$) A number of researchers have pursued the oxides of iron as potential cathode materials for Li-ion cells. The first cathode material produced in this category is $LiFePO_4$ [61]. Its low cost and environmentally benign characteristics could have a major impact in electrochemical energy storage. Orthorhombic $LiFePO_4$ of the olivine structure forms $FePO_4$ during charging/discharging, and two crystal phases exist during charging/discharging; thus, it exhibits a flat discharge curve with a discharge potential of 3.4 V [62]. The specific capacity of $LiFePO_4$ is lower compared to nickel and cobalt-based materials. Substitution of iron by manganese transforms the shape of the charge/discharge curves, and this proved effective in increasing the energy density [63, 64]. The capacities of the lower voltage (3.5 V) and higher voltage region (4.0 V) correspond to the content of iron and manganese. Modified $LiFePO_4$ material too makes it more stable and compatible with a wide range of electrolyte solvents that greatly enhances performance and rate capability.

Mixed Oxide Cathodes

Nickel Cobalt Dioxide, $LiNi_{1-y}Co_yO_2$, and Nickel Cobalt Aluminum oxide, $LiNi_{1-y-z}Co_yAl_zO_2$ In general, the introduction of cobalt into nickel oxide structures leads to more stability and nickel oxide structures are less likely to lose oxygen than the pure nickel oxide, and studies on the structural details and physical properties of the mixed oxide system showed that there is an increased ordering with increase in the cobalt concentration. An issue with all these layered oxides is their electronic conductivity, which is not uniformly high across the lithium composition range or nickel substitution. For example, cobalt substitution in $LiNiO_2$, as in $LiNi_{0.8}Co_{0.2}O_2$, reduces the electronic conductivity at 4.2 V significantly. These dramatic changes demand that a conductive diluent be added to the cathode-active material, which reduces both the energy storage and the power capabilities.

Substituted nickel oxides, such as $LiNi_{1-y-z}Co_yAl_zO_2$ (NCA), are prime candidates for the cathode of advanced lithium batteries for use in large-scale systems as required for hybrid electric vehicles. They currently are the battery of choice for satellite applications. On charging these mixed oxides, the nickel is oxidized first to Ni^{4+} then the cobalt to Co^{4+} [65]. The significant feature of NCA type material is its increased thermal stability by doping with cobalt and aluminum. The temperature of the exothermic peak with oxygen evolution increased from 200°C of $LiNiO_2$

to 310°C of $LiNi_{0.8}Co_{0.15}Al_{0.05}O_2$ due to the decrease in the nickel content and the aluminum doping [66]. The thermal stability has been considerably improved and there is no oxygen evolution observed below 300°C. Moreover NCA type material has a higher capacity, better cycle life and also rate capability than that of the conventional cobalt-based cathode.

Nickel Cobalt Manganese Oxide, $Ni_xCo_yMn_zO_2$ One other commonly used mixed oxide material as positive electrode is cobalt- and manganese-doped lithium nickel oxide. In general, addition of nickel suppresses manganese dissolution to a great extent, thereby enhancing the cycling performance especially at higher temperature. The most common stoichiometry is the 333 compound $LiNi_{1/3}Mn_{1/3}Co_{1/3}O_2$ synthesized using coprecipitation method by Ozhuku et al. [67] and Jeff Dahn in Canada (3 M). There have been many studies on the 333 compound, which have been made by a number of synthetic techniques over a wide range of temperatures. Most of these studies show similar behavior with the capacity of around 165 mAh/g increasing with increasing charging potential [68–70]. The material attracts much attention because of the large battery capacity of about 200 mAh/g, and is a promising material in future. However, the material has certain disadvantages associated with the physical property, namely, lower tap density, smaller particle size that leads to lower energy density and thus mostly preferred to be used in the mixed cathode material. Similar to NCA type material, for the NMC material also, the DSC peak temperature related to the oxygen evolution shifts to the higher temperature as the increase in manganese doping amount and the amount of heat generation decreases extremely. The thermal stability of the cathode material thus could be improved by manganese doping [71].

High-Energy Structured Type and Layered Cathode Materials There are several approaches currently being pursued to improve the cathode energy density, high rate performance, and cycling performance. One of the means to achieve the trade-off properties, namely, higher capacity and superior thermal stability, is through core-shell structured type electrodes. Higher capacity would be delivered by the core material, and structural/thermal stability would be achieved by the shell material [72–74]. A typical example is NCM type material in core to provide higher capacity surrounded by Ni-/Mn-based layered oxide as shell to offer good thermal stability.

One other approach is a composite layered oxide synthesized through continuous, low-cost highly homogenous coprecipitation process that provides higher capacity and cell voltage. One typical example is $xLi_2MnO_3.(1–x)LiNiO_2$ that claims to deliver around 250 mAh/g with longer cycle life and is able to operate at 4.6 V with surface modification [75, 76]. Other approaches include: surface treated cathode like AlF_3-coated cobalt-doped material to improve cycle life and power when operated at elevated temperatures and pseudo co-crystal-like structure with particle surface doping (e.g., $LiCoO_2$ type core material with the surface being treated with dopants like magnesium) to improve stability of the structure. Coating the positive electrode with materials such as Al_2O_3, $AlPO_4$, and ZrO_2 is also being actively pursued and used in commercial Li-ion cells [77–79]. Such surface coatings provide superior charge discharge characteristics, increased rate capability, long cycle life, and enhancement in structural stability, and this also elevates thermal stability.

Electrolyte and Additives

For the battery electrolyte, more focus is on developing additives to carry out additional functions to improve the performance and safety also referred as role-assigned electrolytes. Sanyo [80] and Saft [81] companies were the pioneers in proposing Vinylene carbonate (VC) as a solvent additive for graphite based electrochemical systems. VC is one of a popular additive for battery electrolytes typically being used as an anode passivation film-forming agent offering excellent stability and improvement in cycle life. The addition of VC has shifted the decomposition temperature of the SEI to a higher temperature, and this enhanced thermal stability can explain the suppression of the reaction between the electrolyte and the anode when the SEI is broken and repaired. It is considered that the relatively thinner homogeneous SEI formed by VC is an origin of the better cell performances, although the quality of its SEI is strongly dependent on the kind of graphitic carbons and charging conditions.

Sulfite compounds, namely, ethylene sulfite (ES), propylene sulfite (PS), dimethyl sulfite (DMS), and diethyl sulfite (DES), were also being used as passivation film-forming agents especially for PC-based electrolyte, and these compounds were reduced at about 2 V versus Li^+/Li to form the passivation layers, which hindered the PC co-intercalation into the graphene layers [82–84]. Cyclic sulfonate compounds, namely 1,3-propane sulfone (1,3-PS), were reported to give a good SEI film, which resulted in improving cycle and storage performances of cylindrical hard-carbon/$LiMn_2O_4$ cells [85].

Some key additive materials used as overcharge protection agents include biphenyl (BP), cyclohexyl benzene (CHB), and hydrogenated *m*-terphenyl (H-mTP). BP polymerizes [86, 87] on the positive electrode during overcharge and the liberated protons migrate to the anode, generating hydrogen gas. This mechanism is used for the overcharge protection: In case of cylindrical cells with pressure-activated current intermitted devices (CID), the internal pressure rise by H_2 evolution helps to operate them and prismatic cells utilize the current shutdown mechanism by the increase in the internal resistance by the polymerized film and the meltdown of polyethylene separators [88].

For protecting the cells from overcharge, one other method is including redox shuttle-type compounds as additives in electrolyte. A compound "R" with a reversible redox potential is added to the electrolyte solution. The R is oxidized to compound "O" on the positive electrode, and then O migrates to the negative electrode and is reduced to the original form R. The requirements for such a compound are that the redox potential should be slightly positive (0.1–0.2 V) to the formal potential of the positive electrode at the end-of-charge and the redox reactions during overcharge should be kinetically reversible on both the electrodes. Some examples include aromatic compounds like 2,4-difluoroanisole (DFA) [87], 4-bromo-1,2-dimethoxybenzene [89], and 2,7-dibromothianthrene [90].

Wetting characteristics are very critical for cell design to obtain optimal performance. In general, one might expect that the solvents and liquid electrolytes will be attractive to hydrophilic surfaces such as cathode materials, but repulsive to hydrophobic ones such as polyolefin separators and carbonaceous anode materials [91]. The separator wettability can limit the performance of batteries by increasing the separator and cell resistance. The contact angle is a good measure of wettability. The uptake of electrolyte can be enhanced by wetting agents such as methyl phenyl carbonate (MPC) [92] and di-octyl carbonate (DOC) [93].

The additives used in electrolyte as a flame-retarding agents include trimethyl phosphate (TMP), phosphazene derivatives, namely, hexamethoxycyclotriphosphazene (HMPN), tris(2,2,2-trifluoroethyl) phosphate (TFP), and hexamethylphosphoramide (HMPA). Due to the passivation layer formed by these flame-retarding additives [94–96], the exothermic peaks were depressed and also the self-heat rate occurring at elevated temperature thereby provided safety during abuse situations. In addition fluorinated ester group materials (e.g., FEC) are also being used as additive to electrolyte to improve upon high-temperature stability [97–99]. There are also several ongoing research activities on molten salt electrolytes to gain the benefits of the nonflammable characteristics, but overcoming the conductivity issues is still challenging.

Separators

The process for making Li-ion battery separators can be broadly divided into dry and wet processes. Both processes usually employ one or more orientation steps to impart porosity and/or increase tensile strength. Dry process involves melting a polyolefin resin, extruding it into a film, thermal annealing to increase the size and amount of lamella crystallites, and precisely stretching to form tightly ordered micropores. In this process, a row lamellar crystal structure is generated in the polymer in the initial extrusion step. This nonporous structure is highly oriented as a result of extrusion and annealing conditions. In the next step, film is stretched to form micropores. This microporous structure is continuous throughout the bulk interior of the membrane. No solvents are required to produce separator membranes through dry process method.

Wet process also called as phase inversion process involves mixing of hydrocarbon liquid or some other low-molecular-weight substance generally with a polyolefin resin, heating and melting the mixture, extruding the melt into a sheet, orienting the sheet either in the

machine direction or biaxially, and then extracting the liquid with a volatile solvent. The structure and properties of the membranes can be changed by controlling the composition of the solutions and the evaporation or subtractions of solvents in the gelation and solidification processes. The separators made by wet process use ultrahigh-molecular-weight polyethylene (UHMWPE). The wet process method is not applicable for polymers such as polypropylene, which do not dissolve in conventional solvents.

Shutdown separators are one of the safety devices inside the cell and act as a last line of defense. The separator shutdown is irreversible, which is fine for polyethylene-based separators, which melt at around 130°C. The impedance of the separator increases by two to three orders of magnitude due to an increase in cell temperature, which results from cell abuse (e.g., short circuit, overcharge). The separator not only should shut down around 130°C, but it also should maintain its mechanical integrity at higher temperatures. The high-temperature melt integrity of separators also is a very important property to keep the cell safe during extended overcharge or during extended exposure to higher temperatures.

Many technology advancements and improvements are achieved for the separators that also enable the Li-ion cell to operate more reliably under wide ranges of voltage and temperature for prolonged cycles. Separators existing in current market exhibit superior uniformity in thickness and pore distribution, higher strength, and dimensionally more stability at elevated temperatures. The separator membrane shows higher thermal stability through blending with high melting polymer resins. Ceramic material coating on top of polyolefin separator is currently becoming a popular choice for large format Li-ion cells for EDV applications to improve safety. Ceramic layer controls the shrinkage of the separator significantly especially at temperatures close to the melting points of polyolefin, thereby enabling the separator to isolate the electrodes for much higher temperatures.

Battery Management Systems

Owing to the fact that no two cells in a battery are exactly identical, their parameters such as capacity, voltage may vary by a fraction even when manufactured under similar conditions with advanced quality control protocols. In the case of a new battery, these factors may not be very noticeable, but play a major role in determining the performance of the pack with continuous charge/discharge cycles. This problem is easier to detect in a battery of up to 6–12 cells as the case in NBPC battery packs. A faulty cell can be easily disguised in a large battery pack consisting of tens or hundreds of series-connected cells as will be used for EDV applications. Thus, it becomes very essential to monitor the batteries individually and detect faults early.

A battery management unit (BMU) monitors and controls a battery pack. To increase the capacity and voltage, cells are connected in series-parallel arrangements. A typical laptop battery pack would contain a total of six 18650 cells where three cells are connected in series and two of the three cell series combination are connected in parallel. This setup is commonly denoted as 3S2P configuration. In the case of electric vehicle applications, it is common to have several hundred cells in series-parallel arrangements to get the desired voltage of 300–400 V and capacity.

The basic functionalities in a BMU consist of safety functions, voltage and current measuring, state of charge (SOC), and temperature monitoring. For Li-ion battery packs, battery management is the most essential as cells are needed to be controlled individually. When all cells are in parallel, the voltages are forced to be equal according to Kirchhoff's circuit laws, and hence, no balancing is needed. When the cells are connected in series, the voltages will differ and hence need balancing.

Cells in a battery pack may have slightly different voltages and capacity after complete charge due to minor differences in capacity, impedance, and rate of self-discharge. Cell balancing has been used to reduce the voltage differences among cells, thereby enhancing capacity and cycle life. Overvoltage safety detection functions will abort charging of the battery when any cell reaches its overvoltage threshold. Therefore, other cells may stay undercharged. One consequence is that the battery's full capacity will not be available for discharge. The same occurs when the weakest cell reaches the lower threshold, resulting in capacity not being

used. Without balancing, the different cell capacities will start to drift with every charge/discharge cycle, leading to a decrease in the battery pack's total performance.

Cell balancing can be carried out using current bypass by burning up energy through a resistor as heat. This is often referred as passive balancing where to even out differences; the lowest cell determines the level of capacity after balancing. Passive balancing shall not be applied during discharge as it reduces the available capacity of the battery. One other means of balancing is active balancing where energy would be passed from a cell with higher voltage to a cell with lower voltage.

In electric vehicle applications, battery management is essential and much more demanding than for portable batteries. It has to interface with a number of other onboard systems, has to work in real time in rapidly changing charge/discharge conditions as the vehicle accelerates and brakes, and it has to work in harsh and uncontrolled environments. Determining the battery state of charge is particularly critical in electric vehicle applications since these batteries require both high-power charge capability (regenerative braking) and high-power discharge capability for start or acceleration. Therefore, they must be maintained at a SOC that allows delivering the required power, while still having enough "headroom" to accept regenerative charge without overcharging the cells.

In addition to current and voltage monitoring, the BMU also monitors the temperature of the cells in all modes of operation (drive, charge, etc.) and controls the pump, fans, and heater to manage the temperature of the battery. Battery thermal management is critical for the battery life and the vehicle performance, and it is done through the battery electronic control unit. The goal is to make a battery pack work at an optimum average temperature (with life and performance trade-off) with even temperature variations in the modules and within the pack.

Glossary

Aneuploid An unbalanced number of chromosomes.

Blastocyst A stage of early development where the embryo contains a fluid-filled cavity and two cell populations: an inner cell mass and an outer layer of trophectoderm cells.

Cell cycle The period between the birth of a cell and its division. During a single cell cycle, the cell must duplicate all of its components, including DNA, to form two equal daughter cells.

Chromatin The combination of DNA and proteins, mostly histones.

Cytoplast An enucleated cell used as a recipient for a donor nucleus. Generally in SCNT, the recipient cytoplast is an enucleated oocyte.

Diploid The cell or nucleus contains two complete copies of the genome or a complete complement of chromosomes (2n), in general, a single maternal and a single paternal.

Donor cell The cell that provides the genetic material (nucleus) for SCNT. The resulting animal will be a genomic copy of the animal from which this cell was collected.

Haploid The cell or nucleus contains only a single copy of the genome or half of the chromosome complement (n). Pronuclei are, in general, haploid, containing either a single maternal genome or a single paternal genome.

Karyoplast A cell or a membrane-bound portion of a cell containing the donor nucleus enclosed. In livestock SCNT, the karyoplast is generally an intact cell.

Meiosis The process of reduction in the number of chromosomes that occurs during germ cell formation. Following a round of DNA synthesis, a single cell undergoes two rounds of division resulting in four cells, each containing a haploid genome. During division, independent assortment of parental chromosomes and homologous recombination generate a unique haploid genotype in each of the germ cells.

Metaphase II (MII) Stage during the second meiotic division where the chromosomes are aligned at the metaphase plate prior to segregation of sister chromatids to opposite poles. In most mammalian species, mature oocytes arrest at MII and meiosis is reinitiated and completed upon fertilization.

Parthenote An unfertilized zygote produced by activation of an oocyte. A parthenote may be haploid or diploid for maternal DNA, a gynogenote, or following enucleation and replacement with paternal DNA, an androgenote.

Tetraploid The cell or nucleus contains four haploid copies of the genome (4n).

Zygote The 1-cell stage of development of a fertilized embryo. During most of the first cell cycle, the zygote will contain two pronuclei containing the maternal and paternal DNA.

Definition of Cloning and SCNT

Cloning is the production of genetically identical individuals by the process of asexual reproduction. In animals, the term has been applied to offspring that are produced by the technique of nuclear transfer (NT). The process of nuclear transfer involves the production of an embryo by transferring nuclear genetic material from a donor cell (karyoplast) into a recipient cell from which the genetic material has been removed (cytoplast). Two factors determine the clonality of the resultant offspring. One is the recipient cell, generally an oocyte or unfertilized egg obtained from an unrelated animal. The second is the donor cell, which can be obtained from a variety of sources including embryos, germ line, and somatic tissues of fetuses and adult organisms. When cells from somatic tissues are used, the procedure is termed somatic cell nuclear transfer (SCNT). In most species, transfer of the donor nucleus is primarily carried out by cell fusion with fewer reports of direct injection. In the case of fusion, the complete contents of the donor cell are introduced into the recipient cell, while in the case of injection, the donor nucleus might be accompanied with a proportion of the donor cytoplasm.

While SCNT became publicly known with the creation of Dolly the sheep in 1997, NT was already in the

realm of science since 1928, with the first successful SCNT experiments carried out in frogs in the late 1950s. By creating a genetic copy of a known animal, SCNT opens many opportunities in several fields including biomedical research and agriculture.

Introduction: Embryo Development and Highlights of NT

In animals, reproduction occurs primarily by sexual means, resulting in the creation of a new individual that contains genetic material (DNA) from two contributing parents of different sexes, each parent contributing half of the genetic material. Conception of a new individual occurs by the fusion of specialized cells or gametes, sperm in males and ova in females. Sperm are haploid (n) and contain a single copy of the genome, meanwhile ova, in most species, at the time of fertilization are arrested in metaphase of the second meiotic division and are diploid (2n). After fusion, however, the ovum completes meiosis to become haploid, and the resultant zygote is diploid (2n), containing a full set of chromosomes derived from both parents. The ovum is a large cell that contains sufficient maternally derived proteins and mRNAs to control early development. Following fertilization, during the early stages of development, no net growth occurs (Fig. 1); transcription from the embryonic genome is low but subsequently increases rapidly at a particular stage termed maternal to zygotic transition (MZT) [1]. The timing of the MZT is species dependent, for example, in mice, it occurs at the 1–2-cell stage; in pigs and humans at the 4–8-cell stage; in cattle and sheep at the 8–16-cell stage; while in the amphibian *Xenopus laevis*, it occurs approximately at the 4,000-cell stage [2]. After this transition, the embryonic genome orchestrates its own development. The embryo continues to increase in cell number within the confines of the zona pellucida (ZP), which acts as a protective shell. By the blastocyst stage, a fluid-filled cavity, called blastocoel, has formed and two distinct cell populations have emerged: the inner cell mass (ICM) and the trophectoderm (TE). As the blastocyst expands, build-up pressure together with the secretion of enzymes causes the ZP to break, enabling the blastocyst to hatch. Now the blastocyst is ready to interact with the endometrium and eventually to implant. By cell proliferation and differentiation, the ICM will form the fetus and some extraembryonic tissues while the TE will give rise to most of the placenta (Fig. 1).

The zygote is a totipotent cell, having the capacity to produce the fetus and the placenta. In contrast, sperm and ova are specialized cells. How do they acquire totipotency? Following fertilization, unknown factors present in the ovum's cytoplasm reprogram the paternal and maternal genomes so that their specialized gamete functions are erased to give way to an embryonic totipotent genome. This capacity to reset a specialized genome into a less specialized or totipotent genome is termed nuclear reprogramming. It is this nuclear reprogramming ability of the ovum that is harnessed in NT technology.

The first rudimentary NT experiments were performed by Hans Spemann in 1928. He used a donor nucleus from a 16-cell embryo and a presumptive zygotic cytoplast, resulting in a normal salamander [3]. Interestingly, Spemann had already predicted the possibility of cloning an adult animal by doing NT with an adult donor nucleus in what he termed the "fantastical experiment" [3].

In 1952, Briggs and King used NT to address the question of nuclear equivalence, that is, whether or not the different cells of a multicellular organism have the same genome. They developed the NT procedure by transplanting nuclei from frog blastula cells into enucleated oocytes [4]. Later on, Briggs and King tested the nuclear equivalence of more developmentally advanced frog cells and found that the developmental potential of reconstructed embryos gradually declined with increased donor cell differentiation [5]. However, John Gurdon pushed the field further by generating cloned adult frogs from differentiated epithelial somatic cells at the tadpole stage [6, 7], providing strong evidence for nuclear equivalence. Thus, the first successful SCNT had been achieved, but attempts to clone adult frogs failed [8].

Nuclear transfer in mammals lagged behind, with the first attempt in 1975 using morula-stage blastomere donors and unfertilized rabbit eggs. Even though the extent of reprogramming required for a blastomere, compared with a fully differentiated cell, is quite reduced, the reconstructed cloned embryos did not develop beyond the early cleavage stages [9]. In 1983, McGrath and Solter transplanted zygotic nuclei into

Livestock Somatic Cell Nuclear Transfer. Figure 1 (Continued)

enucleated zygotes resulting in mice developing to term, showing that the technique of nuclear transfer in mammals was feasible [10]. However, such a zygotic nuclei-replacement experiment did not involve any nuclear reprogramming, and when the same approach used more developmentally advanced blastomere nuclei as donors, it failed [11]. This failure in mice NT was followed by several breakthroughs in which enucleated oocytes were used as recipients of blastomere nuclei, leading to the production of cloned animals in sheep [12], cattle [13], and pigs [14]. In contrast to McGrath and Solter's failure in cloning mice, these results suggested that the enucleated oocyte is a better recipient than the enucleated zygote for reprogramming the donor blastomere nucleus.

Ten years passed until another breakthrough advanced the field of mammalian nuclear transfer: Keith Campbell and colleagues at the Roslin Institute succeeded in cloning a lamb by NT using donor nuclei from an established cell line derived from embryos [15]. In this study, cell cycle coordination between the donor cell and recipient oocyte was carried out prior to NT in order to improve the development of reconstructed embryos as previously determined by this group [16, 17]. One year later, this same group, led by Ian Wilmut, used a similar approach and shook the world's news with the creation of "Dolly" the sheep, the first mammal to be cloned from an adult somatic cell [18]. This study showed that an adult somatic cell retains all the information necessary to generate a new organism. After the creation of Dolly, much research has been done in SCNT and several species have been cloned from adult cells. Despite advances in the field,

Livestock Somatic Cell Nuclear Transfer. Figure 1
Flow diagram illustrating mammalian development. Following fertilization of the MII oocyte by sperm, a zygote with the two parental pronuclei is formed. By cleavage, the embryo develops sequentially through the 2-cell, 4-cell, 8-cell, 16-cell, morula, and blastocyst stages. By the blastocyst stage, the first differentiation event has formed the inner cell mass (ICM) and the trophectoderm (TE). These two cell populations will form the foetus and placenta, respectively

the frequency of development of embryos produced by SCNT remains low, with only 1–10% reaching term, depending on the species. Moreover, many cloned animals are born with abnormalities.

Applications of Livestock SCNT

Soon after the arrival of Dolly came the realization that SCNT had several potential applications. For instance, derivation of embryonic stem (ES) cells from human blastocysts was eagerly sought for regenerative medicine research. The rationale was that cells from a patient could be used for SCNT to derive ES cells, which in turn could be induced to differentiate into a specific tissue. Since such a tissue would be genetically identical to the patient, it could replace a damaged tissue in the same patient without the risk of immune rejection. Due to the ethical concerns of destroying human embryos, SCNT for regenerative medicine has been fiercely opposed. Fortunately, this problem seems mostly circumvented with the revolutionary creation of induced pluripotent stem (iPS) cells [19]. These cells have similar properties to ES cells and can also be derived from the somatic cells of a patient without the use of human oocytes or embryos. Since then, much of the field of regenerative medicine research has shifted from SCNT to iPS cell technology. However, recent studies have found genetic and epigenetic abnormalities in iPS cells [20–22], making them potentially unsafe for medical uses. Whether or not iPS cells are inferior to ES cells is currently the focus of heated debate. Since some of the problems found with iPS cells have not been reported with ES cells derived from SCNT embryos [23, 24], the process of nuclear reprogramming occurring in the oocyte appears to be of better quality than the one taking place during the derivation of iPS cells. Very little is known about the mechanism of nuclear reprogramming and the factors present in the oocyte responsible for triggering or carrying out such process. If these factors are found, they could potentially contribute to generate safer iPS cells for regenerative medicine. Thus, further research in the mechanism of nuclear reprogramming following SCNT is needed.

Apart from being a useful tool for basic research with potential indirect applications in regenerative medicine, SCNT has wide applications in agriculture. For instance, an animal of exceptional productivity can be multiplied by SCNT to increase commercial output or to reduce environmental impact. However, caution must be taken with such approach. First, consumption of products derived from cloned animals is not yet widely accepted by the public, and in some countries, there are regulations forbidding their entry into the human food chain. Second, the SCNT technology is so inefficient at present that its application for livestock multiplication might not be economically justified. Finally, it is important to keep in mind that clones are not necessarily true copies of their donor because of epigenetic differences, which result from faulty nuclear reprogramming following SCNT (discussed later). Slight epigenetic differences can affect the physiology of the cloned animal and thus its productivity. Such consideration should especially warn breeders of race-winner horses, as a cloned horse is unlikely to be a winner again.

A more realistic agricultural application of SCNT is to reproduce animals of high genetic value for breeding purposes. For instance, a prizewinning bull could be cloned and subsequently produce thousands of offspring by artificial insemination. To a lower extent, the genetic value of a cow could also be disseminated by SCNT followed by artificial reproductive technologies. While there might be risks associated with consumption of products from cloned animals due to potential epigenetic errors originated during nuclear reprogramming, their offspring should be safe since epigenetic and imprinting errors are normally erased during gametogenesis.

More importantly, SCNT has represented a great technical advance in the production of transgenic animals (this is discussed in detail in the entry ► Nuclear Transfer to Produce Transgenic Mammals, this volume). In turn, transgenic animals have a myriad of other applications, which are discussed throughout this volume. Furthermore, transgenic animals producing pharmaceutical or novel proteins are good candidates for multiplication by SCNT since the cost of using this technology would be relatively small compared to the product harvested from the cloned animals.

SCNT can also be used for cloning individuals from an endangered species population. Examples of this application include the cloning of wild cattle (Gaur and Banteng) and wild sheep (European Mouflon) [25].

These examples resorted to interspecies SCNT in which a close-related species is used as cytoplasmic recipients and surrogates for the donor. Therefore, the resultant offspring will be a hybrid containing a genomic copy of the endangered donor and most mitochondrial DNA (mtDNA) from the close-related recipient. While the physiological consequences for this are unclear, it certainly raises ethical issues. Besides, other efforts such as restoration of the natural habitat and assisted breeding programs are likely to be more effective at helping an endangered population.

Taken together, SCNT has some interesting applications, but the ethical implications surrounding this technology must be fully considered before rushing into implementing SCNT in the field. Rather than an end, SCNT is especially useful when used as a tool in research, production of transgenic animals, and in cloning of prizewinning animals for breeding purposes in agriculture.

NT Techniques

NT is a complex multistep procedure, with several alternatives at some steps, which include oocyte maturation, cumulus cell removal, enucleation, nuclear transfer, activation, and embryo culture. Culture of the donor cells is important and usually accompanied with cell-cycle synchronization prior to NT. Enucleation and nuclear transfer are the most important and difficult steps. To carry out these steps, most laboratories use micromanipulators. A micromanipulator is a relatively complex instrument composed of a microscope, micromanipulators at both sides to hold the holding and injection micropipettes, micromanipulator joysticks to precisely maneuver the micropipettes in three dimensions, and microinjectors to precisely aspirate and expel fluid and cellular material from the micropipettes. For mice cloning, microinjectors are usually equipped with piezoelectric devices to prevent lysis of the fragile mouse oocyte during enucleation and nuclear transfer. An alternative to micromanipulators is a technique called handmade cloning (HMC) and seems equally efficient as micromanipulator-based NT (for a review of HMC, see [26]). Following is a brief discussion of the different steps involved in the entire NT procedure with focus on livestock species unless stated otherwise.

Oocyte maturation is usually required in livestock cloning as immature oocytes are commonly obtained from ovaries collected from slaughterhouses. Alternatively, in vivo–matured oocytes can be obtained by stimulating superovulation, which is followed by oviduct flushing after slaughtering the animal. In vitro maturation (IVM) entails mimicking to some extent the in vivo environmental conditions found in the ovary at the time of the LH (luteinizing hormone) surge. Thus, three key hormones, LH, FSH (follicular stimulating hormone), and estradiol, are added to the IVM medium to stimulate maturation. Oocytes are surrounded by cumulus cells, forming a cumulus-oocyte complex (COC); cumulus cells aid oocyte maturation. COCs are incubated at about 39°C in livestock species and for 24 h (e.g., cow and sheep). Following the required maturation period, oocytes are denuded from the cumulus cells using hyaluronidase to digest the extracellular matrix that holds cumulus cells together. Removal of cumulus cells is necessary to allow visualization of the oocyte's chromatin during enucleation and to prevent inserting a cumulus cell accidentally inside the oocyte during enucleation and cell/nuclear transfer procedures. Now the denuded oocytes are ready for enucleation.

A few enucleation methods exist. The most commonly employed method uses micromanipulators to aspirate the chromatin. In this method, the oocyte is held steady at one side with the holding pipette while the enucleation pipette is inserted from the opposite side to remove, depending on the maturation state, the extruding spindle or first polar body together with the metaphase plate (Fig. 2). In order to confirm enucleation, it is desirable to visualize the chromosomal material. In mice and human oocytes, which have a clear cytoplasm, chromatin can be readily observed under bright field illumination. However, the oocytes of livestock species have high lipid contents that hamper chromatin visualization, and therefore, enucleations must be made "blind" (Fig. 2a). Generally, to aid enucleation of livestock oocytes, they are briefly preincubated with the vital DNA stain Hoechst. The stained karyoplast is confirmed in the enucleation pipette by UV light following enucleation. Although this procedure does not expose the oocyte to direct UV irradiation, conflicting evidence exist whether Hoechst diminishes the developmental competence of the oocyte.

Livestock Somatic Cell Nuclear Transfer. Figure 2 Diagram illustrating enucleation of livestock oocytes. (**a**) When enucleation is carried out at metaphase II (*M*II), the polar body (*PB*) and a portion of cytoplasm is blindly aspirated to remove the underlying MII plate. Chromatin cannot be observed under bright field illumination, thus UV light exposure (*dark field*) is essential to confirm enucleation of the pre-stained chromosomes. (**b**) When enucleation is carried out earlier at anaphase I/telophase I (AI/TI), the extruding spindle is aspirated. In contrast to MII enucleation, the AI/TI spindle can often be observed directly inside the enucleation pipette. However, enucleation of pre-stained DNA can be checked with UV light. In both enucleation methods, the oocyte is removed from the field of view to avoid damage by direct UV irradiation when exposing the enucleation pipette

Alternatively, a blind-enucleation method without DNA staining uses the first polar body as a point of reference to subsequently remove the underlying metaphase II (MII) plate. Unfortunately, the MII plate can shift away from the polar body, rendering its removal inaccurate. However, when blind enucleation is performed earlier at anaphase I/telophase I (AI/TI) stages of the cell cycle, removal of the complete spindle is close to 100% accurate (Fig. 2b) [27]. A newer microscopy technology based on birefringence, the PolScope, allows noninvasive visualization of spindles not only in human oocytes but in other species as well. Probably due to the high cost of the PolScope, this enucleation method has not gained much popularity.

Direct enucleation by aspiration can be chemically assisted with cytoskeleton-relaxing agents, resulting in a protrusion cone containing the oocyte's chromosomes. Drugs used for this purpose include demecolcine and nocodazole, both interfering with microtubule polymerization. Other enucleation methods that have been attempted are centrifugation and laser ablation. In HMC, the zona pellucida is digested, and one third of the oocyte containing the extruding polar body and metaphase plate is manually bisected with a microblade under a stereomicroscope.

Donor cells are usually cultured in vitro and synchronized in a specific phase of the cell cycle prior to NT in order to ensure a known ploidy content. In livestock species, donor cells are preferentially used in G_0 and, to a lower extent, in G_1. Quiescent G_0 cells are arrested in the G_1 phase of cell cycle by either serum starvation or cell-contact inhibition. The advantage of these two methods is that they are drug independent, while methods to arrest cells at G_1 usually require the use of pharmacological agents. Alternatively, actively dividing presumptive G_1 cells can be selected by collecting small-sized cells. A more accurate drug-free method to select for G_1 cells from actively dividing cultures involves using the eukaryotic "baby machine", which briefly consists of an effluent that collects newly divided and floating daughter G_1 cells from the culture medium (this methodology is described in [28]). Such a methodology would be especially useful when it is desirable to clone ES cells in G_1 (discussed further in the section Coordination of Donor and Recipient Cell Cycles). In mice cloning, ES cells are often arrested in metaphase by nocodazole or colcemid treatments.

Livestock Somatic Cell Nuclear Transfer. Figure 3
Diagram illustrating different methods for donor genome transfer into recipient enucleated oocytes. (**a**) In cell transfer, an intact donor cell is transferred into the perivitelline space and the genome is then incorporated into the recipient by cell fusion. (**b**) In nuclear microinjection, nuclei are previously isolated and a single nucleus is then microinjected into the recipient. (**c**) In whole-cell microinjection, the whole cell is injected into the recipient. Eventually, incorporation of the genome into the recipient occurs by spontaneous degradation of the donor plasma membrane. (**d**) In chromosome transfer, a broken mitotic cell is microinjected into the recipient to transfer the mitotic spindle

A few alternatives exist for inserting the donor nuclear material into the enucleated oocyte (Fig. 3). In livestock species, the most common method is to insert the whole donor cell (cell transfer) into the perivitelline space to achieve contact between the membranes of donor and recipient cells. The donor DNA is then incorporated into the enucleated oocyte by cell fusion (Fig. 3a) (discussed below). Another method is to directly insert the nucleus (nuclear microinjection) into the enucleated oocyte, a common practice in mice cloning (Fig. 3b). The advantage of this method is that it bypasses the need for fusion. Nuclei are isolated using a micropipette with an inner diameter smaller than the donor cell. Pipetting the cell in and out breaks the membrane and releases the nucleus. Interestingly, it is also possible to microinject the whole cell into the enucleated oocyte cytoplasm, thus bypassing the need for nuclear isolation or fusion (Fig. 3c). Although it is unclear how the donor plasma membrane is degraded, high blastocyst development has been reported with this technique [29]. Another alternative method is to directly microinject a broken cell containing mitotic chromatin and cytoplasm, known as chromosome transfer (Fig. 3d). In HMC, phytohemagglutinin is used to glue the donor cell to the enucleated oocyte, followed by fusion.

When cell transfer is employed, the recipient-donor couplet must be fused to deliver the donor chromatin into the recipient oocyte. This is commonly achieved by electrofusion. In this method, the couplet is placed between two electrodes and short electric pulses are applied to fuse the recipient-donor membranes together. A second method involves the use of inactivated sendai virus (SV). Donor cells are briefly incubated in a solution containing SV prior to cell transfer, achieving oocyte-cell fusion by viral particles. SV-mediated fusion is less laborious and might be less stressful to the reconstructed embryo than electrofusion [30].

Once the donor chromatin has been incorporated into the enucleated oocyte, the reconstructed embryo is activated to begin development. The reconstructed embryo is then ready for embryo culture. Different methods of activation and embryo culture are discussed later in this entry in relation to how they affect NT outcomes. When cloned embryos reach the blastocyst stage in vitro, they are transferred to surrogate females to carry the pregnancy.

Hormonal treatments must be administered to the surrogate so that the "uterine cycle" is synchronized with the developmental stage of the transferred embryo. If this is not properly planned, the uterus will be "out of phase" compared to the blastocyst and implantation will likely fail. To achieve synchrony, in farm animals, the surrogate must be induced to enter estrus on the day of NT. Following transfer to surrogates, care of the embryos is shifted to the hands of the veterinarian. Management of pregnancy includes ultrasonography, to check pregnancy status, as well as measuring maternal levels of pregnancy proteins to assess placental development.

Problems of Cloning

Despite advances in the field, the efficiency of SCNT technology remains very low, with only 1–10% of transferred embryos reaching term, depending on the species. More than 50% of pregnancies are lost in the first trimester, and in contrast to IVF pregnancies, losses of clone pregnancies continue throughout gestation (e.g., [31]). Additionally, developmental abnormalities are commonly observed in cloned fetuses and in their placentas.

During mammalian embryogenesis, the fetus is derived exclusively from the inner cell mass (ICM) while extraembryonic tissues, including the placenta, are mostly derived from the trophectoderm (TE). It is thought that the extraembryonic membranes are the most negatively affected by SCNT, including the placentas of full-term clones. Although cloned fetuses and offspring can present abnormalities as well as large offspring syndrome (LOS), these seem to be secondary to placental dysfunction, which leads to imbalances in placental fluid and in kidney function [32]. In sheep, placental abnormalities include a hypotrophic trophoblastic epithelium, reduced vascularization, and thickening of the trophoblast basement membrane [33]. Placentomegaly (enlarged placenta) is a common occurrence in mice and cattle cloning. Other placental abnormalities in bovine cloning include edema and hydroallantois. Developmental failure can account for fetal losses, stillbirth, and even postnatal mortality of mice, cattle, and sheep. Postnatal mortality is particularly pronounced in cloned sheep [34].

A recent study showed that indeed defects in the trophectoderm lineages rather than in the ICM are the main cause of low cloning efficiencies, at least in mice [35]. This experiment used chimeric aggregates of diploid and tetraploid embryos (Fig. 4). Tetraploid embryos are obtained by fusing the two blastomeres of a two-cell embryo. NT-ICMs were aggregated with tetraploid fertilization-derived (4nFD) early-cleavage-stage embryos. In this diploid/tetraploid "chimera," the 2n NT-ICM cells can only develop into the fetus while the 4n cells can only give rise to the extraembryonic tissues (although minimal cross-contribution was observed). By this approach, a sixfold increase in development to term was obtained compared with the nonaggregated NT control. Moreover, when ICMs from normally fertilized embryos were aggregated with tetraploid NT embryos, the birth rate was similar to that of the NT control, indicating that a normal ICM does not rescue the developmental potential of the reconstructed embryo. However, FD-ICM/4nFD aggregates showed twice the developmental rate than NT-ICM/4nFD. Thus, while trophectoderm defects are mainly responsible for low cloning efficiencies in mice, the ICM has a minor contribution as well.

Livestock Somatic Cell Nuclear Transfer. Figure 4
Experimental evidence shows that the trophectoderm lineage is severely affected in mice cloning. A diploid (2n) ICM and two tetraploid (4n) 4-cell embryos were aggregated from cloned and fertilized embryos in different combinations. The ICM forms the embryo while tetraploid blastomeres can only give rise to extraembryonic tissues. Development to term demonstrated that replacing the trophectoderm lineage in cloned embryos dramatically improves development

It is generally thought that the low cloning efficiencies and developmental problems arise from an incomplete reprogramming of the donor nucleus.

Nuclear Reprogramming

Successful NT experiments demonstrated that differentiated cells (with a few exceptions) retain the same intact genome (i.e., nuclear equivalence) within an organism. In other words, these experiments supported that cell differentiation is not achieved through genetic changes or deletions but rather through epigenetic changes. Epigenetics regulates cell identity through chromatin modifications that are heritable through cell divisions, without altering the DNA sequence. Thus, chromatin modifications establish an epigenetic "code" that results in different gene expression programs between cell types.

Chromatin is formed by DNA associated with histone and nonhistone proteins. The chromatin template is epigenetically modified at the DNA and histone levels. DNA modification is limited to methylation (or demethylation), while histone modifications are numerous, including methylation, acetylation, phosphorylation, ubiquitination, ADP-ribosylation, biotinylation, and sumoylation. In turn, such modifications affect gene expression and the overall chromatin structure, which can be described as open or compact. During normal development, global changes in DNA methylation and histone modifications take place; much effort is being dedicated in understanding how these changes are altered or preserved in cloned embryos.

For SCNT to be successful, it is essential that the chromatin of the donor somatic nucleus is remodeled so that it becomes compatible not only with the totipotent gene expression program of development but also with the rapid cell-cycle dynamics of early embryo cleavage.

Nuclear reprogramming, either following fertilization or SCNT, is the result of active and passive processes. For instance, in most mammals after fertilization, the sperm compact chromatin undergoes active remodeling in which protamines are exchanged by

ooplasmic histones followed by global loss of DNA methylation. The sperm pronucleus also acquires distinct histone marks such as histone hyperacetylation. However, it is not clear whether such modification is acquired actively through the action of enzymes or it is the result of passive acquisition from the ooplasmic histone pool already rich in acetylation marks [36].

The timing required for completing nuclear reprogramming is unclear. Some researchers have suggested that the donor nucleus should be reprogrammed upon reaching embryonic genome activation. Such a restrictive reprogramming timing would be consistent with the lower cloning efficiencies usually observed in mice compared to bovine, two of the most cloned animals, the latter having more time for reprogramming the differentiated donor nucleus before genome activation. However, it has also been suggested that reprogramming continues up to the blastocyst stage.

To better understand the nuclear reprogramming process, the dynamics of the most important epigenetic marks and of gene expression during early embryogenesis in fertilized and cloned embryos are discussed next.

Reprogramming of DNA Methylation

DNA methylation is a reversible modification of the chromatin template at the DNA level in which a methyl group is predominantly added to cytosine of the dinucleotide sequence CpG. DNA methylation is a widely used mechanism of epigenetic regulation commonly associated with stable heritable gene silencing, heterochromatin, chromosome stability, genomic imprinting, X-chromosome inactivation, and inactivation of retroviral sequences. It has been shown that DNA methylation is essential for embryonic development, especially at postimplantation stages [37]. DNA methylation is carried out by DNA methyltransferases (DNMTs). DNMT1 maintains DNA methylation patterns after DNA replication by using the old strand as a template to methylate the new strand. De novo DNA methylation is carried out by DNMT3a and DNMT3b.

DNA methylation is dynamically regulated. Removal of methyl groups can be an active process when specific DNA demethylases are involved to remove the methyl groups, or it can be a passive process when failure to copy the methylation marks on the newly synthesized DNA leads to erasure of those marks during cell divisions. In contrast to DNA demethylation of the sperm pronucleus, which is thought to be an active process [38], passive DNA demethylation of the embryonic genome takes place following the zygotic stage.

After SCNT, DNA methylation reprogramming is usually inefficient. Mice and bovine cloned embryos have aberrantly hypermethylated DNA [39]. In sheep, SCNT embryos also tend to be significantly hypermethylated compared to fertilized embryos [40]. Such abnormal hypermethylation was observed from the 1-cell to the 8-cell stage and then at the blastocyst stage, in which the trophectoderm was hypermethylated relative to the fertilized control.

Interestingly, the rate of demethylation is similar in both SCNT and fertilized embryos, suggesting that the hypermethylated DNA pattern of SCNT embryos is probably inherited from the hypermethylated donor cell [38]. Alternatively, it has been suggested that cloned embryos undergo precocious DNA methylation due to the presence of DNMT1 associated with the donor nucleus, thus preventing passive demethylation [39].

DNA methylation reprogramming appears to be an indicator of developmental potential. In sheep, the proportion of SCNT embryos that were normally methylated at the 2-cell stage coincided with the proportion of surviving embryos reaching the 16-cell stage [38]. Similarly in mice, aberrant methylation of early-cleavage cloned embryos was proportionally associated to developmental failure to the blastocyst stage [41].

Reprogramming of Histone Modifications

The tails of the histone subunits H3 and H4 are targets for chromatin modifier enzymes, with histone methylation and acetylation modifications the most extensively studied. These modifications set epigenetic "marks" associated with either gene silencing or gene activity.

Histone acetylation is associated with open chromatin and gene activity. This modification neutralizes positive charges on histone tails and thus increases the overall repulsive negative charge of DNA on the chromatin structure. In turn, an open chromatin favors the binding of transcription factors to DNA.

In contrast, histone methylation can be either repressive or activating, depending in the lysine residue modified. These modifications act as signals that are "read" by proteins, which in turn can trigger downstream chromatin-modulating events. Together with methylated DNA, methylation of lysine 9 of histone 3 (H3K9), H3K27, and H4K20 has been implicated with heterochromatin and gene repression, while methylation of H3K4, H3K36, and H3K79 is associated with active gene expression.

In addition to abnormal DNA methylation, embryos produced by SCNT show aberrant reprogramming of histone modifications. Asymmetry of H3K9me3 fails to be established between ICM and TE in bovine cloned blastocysts compared with fertilized controls [42]. When histone acetylation marks are compared, however, cloned and normal blastocysts look similar [43, 44], suggesting that these marks are well reprogrammed. Yet, at earlier embryonic stages, the same histone acetylation marks show significant differences, with cloned embryos being hyperacetylated [42, 43].

Deregulation of DNA methylation and H3K9 methylation might be major problems during nuclear reprogramming [38, 42]. Their aberrant reprogramming leads to hypermethylated trophectoderm and extraembryonic tissues. As these epigenetic marks promote inactive chromatin, they are likely to cause downregulation of a substantial number of placental genes, explaining the placental abnormalities frequently reported in cloned embryos.

Reprogramming of Gene Expression

After fertilization or SCNT, the ooplasm induces global remodeling of chromatin, genome silencing, erasure of permissive epigenetic marks of differentiation-associated genes, and resetting the genome to an embryonic state [45–47]. Four classes of genes play an essential role to ensure normal embryogenesis following NT: (1) pluripotency-associated genes, (2) trophectoderm genes, (3) imprinted genes, and (4) differentiation-associated genes. Reactivation of pluripotent and trophectoderm genes must take place, whereas differentiation-associated genes must be silenced. Imprinted genes should be reactivated without altering the normal imprinting of somatic cells.

Pluripotent Genes Pluripotency is the capacity to differentiate into all embryonic cells. The cells of the ICM are pluripotent because they form the embryo. To recognize the state of pluripotency, landmarks of the ICM have been sought, such as stage-specific gene expression or antigens. These landmarks should be associated only with those stages and tissues known to have pluripotent potential such as the cleavage-stage embryo and ICM of the blastocyst. They should not be expressed in differentiated tissues of later development. Key genes associated with the ICM vary with species.

In mice, Oct4 is highly expressed and restricted to the ICM. It plays an essential role in early development as Oct4-depleted mouse embryos fail to form the ICM and are developmentally incompetent [48, 49]. Inducing overexpression of Oct4 is key to revert the gene expression profile of an adult differentiated somatic cell to one of embryonic and pluripotent characteristics [19]. Thus, in the mouse, Oct4 appears to be an ICM-specific marker that can be used to assess pluripotency.

Also in mice, other important pluripotent factors restricted to the ICM are Nanog and Fgf4 [50, 51]. Nanog is involved in maintenance of the pluripotent state of ES cells, for instance, by repressing differentiation into primitive endoderm [50]. Fgf4, a target gene of Oct4 [52], is necessary for proliferation and differentiation of both the ICM into embryonic tissues [53] and the TE into placental tissues [54].

In mouse SCNT blastocysts, Oct4 and Oct4-related genes often fail to be reactivated [55, 56]. Frequently, when Oct4 is expressed, aberrant spatial expression in the trophectoderm indicates faulty reprogramming [55]. Interestingly, when ES cells are used as donors, instead of adult somatic cells, Oct4 and related genes were always expressed in cloned blastocysts [56]. Since pluripotent genes are already active in ES cells, these genes do not need to be reactivated in ES-cloned embryos.

In human and large ungulate mammals, however, it is less clear what master regulatory factors are involved in the segregation of the ICM. For instance, Oct4 is expressed in both ICM and TE of bovine, goat, and human blastocysts [57–60]. Thus, for nonmurine species, we are left with less information to assess the extent of ICM-lineage reprogramming. Yet, Nanog does seem to be restricted to the ICM in bovine [61]

and goats [59]. Similarly, Fgf4 is restricted to the ICM of bovine blastocysts [57]. Therefore, Nanog and Fgf4 are preferred ICM markers to Oct4 depending on the species.

To assess reprogramming of ICM, expression of Nanog and Fgf4 has been measured in bovine cloned blastocysts. Differences between studies were found, with similar [62, 63] and lower levels [57, 64] compared with fertilized controls. The disparity of results may reflect differences in nuclear transfer procedures leading to variable success in reprogramming.

Trophectoderm Genes In mice, the transition from morula to blastocyst that results in the segregation of ICM and TE is regulated by the antagonistic activity of Oct4 and Cdx2, respectively [65]. Together with Cdx2, Taed4, Eomes, and Gata3 are required for specification and development of the TE lineage [66, 67]. Tead4 appears to be a master factor in TE-lineage induction since it activates Cdx2 and Gata3 [67, 68].

Less is known about the mechanism of segregation of the trophectoderm lineage in other mammals. Although CDX2 protein seems to be a conserved TE-restricted marker, as observed in bovine and porcine blastocysts [61], transcripts levels of Cdx2 were also found in the ICM [57]. It is possible that a posttranscriptional regulation mechanism accounts for the difference between gene expression and gene product levels. Thus, to assess reprogramming of Cdx2, it might be more appropriate to look at the protein level. In contrast to mice, Cdx2 does not repress Oct4 expression in bovine [69], explaining why OCT4 is detected in the bovine TE [58]. Another difference between these two species is the expression of Tead4 and Gata3 transcripts, which are found in both ICM and TE of bovine blastocysts, and thus, their role in TE lineage segregation is not clear [57]. Further evidence that bovine TE formation is quite different to mice is the observation that Eomes is not detected in trophoblast tissue [70]. Surprisingly, although bovine TE cells will only contribute to the trophectoderm lineage, they are not committed to it before pregastrulation stages since they were observed to contribute to ICM in aggregation assays [69]. Taken together, these observations suggest that differences in expression of lineage markers between species might be the result of different implantation requirements. For instance, while mouse blastocysts implant readily at this stage, domestic blastocysts undergo elongation and have delayed implantations. Indeed, while OCT4 is expressed in both the ICM and TE of the bovine blastocyst, it is restricted to the ICM lineage at a later elongated stage [71].

Few studies have assessed reprogramming of the TE lineage in cloned embryos. In mice, CDX2 protein was frequently expressed normally at the blastocyst stage [72]. A similar result was found in the bovine [57]. Although reprogramming of Taed4 and Gata3 was faulty in bovine cloned blastocysts [57], these are not specific markers of the TE lineage in the bovine. Therefore, in nonmurine species, assessing reprogramming outcome of the TE lineage is currently limited to measuring CDX2 protein.

Imprinted Genes Imprinted genes are genes expressed either from the paternal or maternal chromosomes, but not both. Gene imprinting plays an essential role in development. When androgenetic (two paternal pronuclei) or gynogenetic (two maternal pronuclei) embryos are produced, embryogenesis is arrested shortly after implantation [73]. Thus, the paternal and maternal genomes have different contributions and must complement each other at fertilization for normal development to occur. Imprinting marks originate during gametogenesis and are generally protected from genome-wide reprogramming, such as DNA demethylation/methylation, during embryonic development [36].

Many imprinted genes regulate development, growth, and function of embryonic and extraembryonic tissues. Following SCNT, many imprinting errors can occur during reprogramming of the somatic chromatin. For an imprinted gene, simultaneous expression from the paternal and maternal alleles or lack of expression is the result of aberrant reprogramming. Because of their regulatory growth function, deregulation of imprinted genes might explain several placental abnormalities and "large offspring syndrome" often observed in cloned animals.

Some researchers have proposed that long-term culture of donor cells, the usual scenario for embryonic stem (ES) cells, is an additional source for imprinting

errors, and thus, it has been suggested that ES cells are a poor choice for NT [74]. However, using microarray technologies, Humpherys et al. [75] found no significant difference between ES-NT and noncultured cumulus cell-NT clones in terms of gene expression abnormalities including imprinted genes. Therefore, it is not clear whether extensive in vitro culture is a major problem for NT in terms of imprinting deregulation. Moreover, mammals seem rather tolerant to imprinting errors [76].

Differentiation-Associated Genes Following SCNT, silencing of differentiation-associated genes is often incomplete. For instance, cloned embryos produced with myoblast nuclei still expressed the myoblast marker GLUT4 [77]. Similar somatic epigenetic memory was also observed in Xenopus cloned embryos, which overexpressed endoderm or ectoderm markers according to the origin of the donor cells [78]. While insufficient silencing of differentiation-associated genes may alter metabolic demands, the functional consequences of retaining expression of somatic genes on the developmental potential of cloned embryos are unclear [46].

Several studies have compared global gene expression profiles between cloned and fertilized embryos. At the 1-cell stage of murine embryos, most transcripts (~98%) were similarly abundant between clones and IVF groups [45], although such similarity might be the result of maternal transcripts abundantly present in the oocyte. Nonetheless, similar expression profiles were obtained between cloned and fertilized blastocysts in bovine (e.g., [63, 79]). Thus, overall gene expression of cloned embryos appears normal. However, it is possible that small alterations in gene expression are amplified during postimplantation stages, which would contribute to the low developmental potential of cloned embryos [79].

In summary, perfect gene expression reprogramming may be unlikely following SCNT. Cell-type-specific genes may be incompletely silenced while imprinted genes are subject to deregulation. Reactivation of ICM- or TE-lineage genes might be problematic depending on the species. The mechanism of nuclear reprogramming is still a black box, and much further research is needed to understand where the bottleneck of NT is.

Factors Affecting Development of Embryos Produced by SCNT

Frequently, reports have shown that there is ample room for optimization in NT technology. Major investigated factors affecting NT success include quality of recipient oocyte, time of enucleation, nuclear donor source, cell-cycle coordination of donor and recipient cells, alterations in the timing and inducer of oocyte activation, and culture of reconstructed embryos.

Sources of Recipient Oocytes

Mammal females produce mature oocytes (oogenesis) during the ovarian cycle. The earliest stage of oogenesis is the primary oocyte within the primordial follicle. Primary oocytes are arrested at the first meiotic prophase in a quiescent state. Some of these are regularly recruited for further growth since puberty and thereafter. As primary oocytes resume growth, they increase in size and undergo cytoplasmic maturation. An oocyte must undergo cytoplasmic and nuclear maturation to be developmentally competent. Cytoplasmic maturation involves mRNA synthesis, translation into protein, and posttranslational modifications. Many mRNA and protein molecules are stored in the cytoplasm to function later during early embryo cleavage, before embryonic-genome activation. Some of the proteins produced, such as maturation promoting factor (MPF), are necessary for meiotic progression during nuclear maturation. Within the follicle, oocyte growth is accompanied with follicular growth. Indeed, oocytes obtained from medium- and large-sized follicles are developmentally better than those obtained from small-sized follicles. It seems that oocytes from the latter group have not completed cytoplasmic maturation [80]. Oocytes are surrounded by cumulus cells, and mutual communication is required for complete oocyte maturation.

Oocytes can be matured in vivo or in vitro. In vivo maturation involves collecting oocytes that have naturally matured within the ovary of a live animal. In contrast, in vitro maturation involves aspirating immature oocytes from the ovaries of slaughtered animals and placing them on favorable culture conditions to complete the maturation process in the incubator. Although much understanding has been gained in oocyte maturation, in vitro maturation is still

suboptimal at best. In vitro–matured oocytes have altered energy metabolism [80], higher chromosomal abnormalities [81], and lower developmental competence than in vivo–matured oocytes [82, 83].

For convenience, in livestock cloning, in vitro maturation is widely used as very large numbers of immature oocytes can be obtained from slaughterhouses at low cost. However, the poorer quality of these oocytes is likely to contribute to the low frequency of development usually observed in cloned embryos.

Enucleation of Recipient Oocytes

Nuclear maturation is resumed at the time of the LH surge in vivo or during in vitro conditions. The oocyte continues meiosis to progress from the arrested prophase I to metaphase I, anaphase I, telophase I, and cytokinesis with unequal cytoplasmic distribution, when half of the chromosomes are discarded in the first polar body. The oocyte progresses to meiosis II and is arrested at metaphase II. Following fertilization or artificial activation, the metaphase II–arrested oocyte resumes meiotic progression once more to complete metaphase II, anaphase II, and telophase II, discarding again half the number of chromosomes in a second polar body, achieving a haploid number of chromosomes. Enucleation can be carried out at any of these meiotic stages, although with possible different consequences (discussed later). Table 1 provides some examples of cloning experiments carried out using recipients enucleated at different stages of meiosis or mitosis.

For NT, it is most important that the oocyte undergoes cytoplasmic maturation to construct a developmentally competent embryo, while nuclear maturation is less important because the oocyte DNA is eliminated at enucleation and does not form part of

Livestock Somatic Cell Nuclear Transfer. Table 1 Examples of cloning experiments using recipients at different meiotic and mitotic stages of the cell cycle

Recipient cytoplast	Donor cell type	Species	Offspring	References
Enucleated GV oocytes (subsequently matured)	ES cells	Mouse	No	[84]
Enucleated Pro-MI oocyte (subsequently matured)	ES cells	Mouse	Nd	[84]
Enucleated AI/TI oocyte (subsequently matured)	Fetal	Sheep	Yes	[85]
	Adult	Sheep	Yes	
Enucleated MII oocyte	Embryonic, fetal, adult	Sheep	Yes	[18]
Unenucleated MII oocyte (subsequent enucleation)	Cumulus cells	Mouse	Yes	[86]
Enucleated activated MII oocyte	Blastomeres	Sheep	Yes	[17]
Enucleated PN Zygote	PN karyoplast from zygote	Mouse	Yes	[10]
	PN Karyoplast from first NT embryo	Pig	Yes	[87]
	Blastomeres	Mouse	No	[11]
	Cumulus cells	Mouse	No	[88]
TII enucleated oocyte	Blastomeres	Goat	Yes	[89]

the embryo. Enucleation of prophase I oocytes, also known as germinal vesicle (GV) stage, has been attempted in the mouse, and the resultant recipients were capable of reprogramming donor nuclei [84, 92]. However, the reconstructed embryos are developmentally incompetent even when recipients are further matured in vitro prior to NT [84]. It is possible that GV oocytes are poor recipients because removal of their transcriptionally active chromatin [93] prevents synthesis of new mRNA necessary for completing cytoplasmic maturation. Similarly, enucleation of pro-metaphase I (pro-MI) oocytes also results in poor recipients [84]. Beyond interfering with mRNA synthesis, it is also likely that enucleated GV and pro-MI oocytes are poor recipients because enucleation disaggregates the cumulus-oocyte complex, thus depriving the oocyte of the beneficial communication with cumulus cells for completing cytoplasmic maturation during in vitro maturation.

Enucleation of metaphase II–arrested oocytes is the most common practice in cloning experiments. The rationale of using such recipients is evident as the COC is left undisturbed during the entire in vitro maturation period, thus maximizing the probability of cytoplasmic maturation. However, a practical alternative is to enucleate at anaphase I/telophase I (AI/TI). By doing so, the spindle is more efficiently removed along with less cytoplasm compared to MII enucleation [27]. AI/TI cytoplasts are further cultured to complete the maturation period and have produced lambs after SCNT [85].

Other recipients have been used for NT. Activation of MII oocytes with subsequent enucleation at anaphase II/telophase II has been done for practical reasons similar to those of AI/TI enucleation [89, 94]. Zygotes and two-cell embryos have also been enucleated and used as recipients for NT. These will be better discussed below in relation to the "potential loss of reprogramming factors" during enucleation and later in relation to the "coordination of donor and recipient cell cycles."

Potential Loss of Ooplasmic Reprogramming Factors

Enucleation involves removing the DNA material from the unfertilized or fertilized oocyte plus an unavoidable volume of ooplasm. It has been speculated that loss of ooplasmic volume is accompanied with a reduction of developmental potential, possibly due to the removal of cytoplasmic reprogramming factors. However, fusion of two or more cytoplasts prior to NT did not improve the frequency of development in mice [95]. Apparently, the amount of cytoplasmic factors in the oocyte is not critical for cloning success.

However, the above discussion does not take into account that the content of reprogramming factors in the cytoplast is dependent on the cell-cycle phase. The genome can be removed as interphase pronuclei in zygotes or with the spindle if recipients are mitotic zygotes or meiotic oocytes. In the latter case, the components of the nucleoplasm stay in the recipient as they are diluted in the cytoplasm following nuclear envelope breakdown. Recipient zygotes enucleated at interphase can only support development of nuclei obtained from 1-cell or 2-cell embryos [11] but fail consistently when more differentiated donor nuclei are transferred [11, 96, 97]. Kevin Eggan and colleagues have shown that zygotes and 2-cell embryos at the mitotic phase regain the reprogramming ability [90, 91]. These authors have proposed that reprogramming factors are sequestered in the nucleus during interphase but then redistributed throughout the cytoplasm during M phase [98]. Therefore, reprogramming factors would be lost when enucleation is carried out during interphase [99]. Indeed, Brg1, a component of the Swi/SNF chromatin remodeling complex necessary for embryonic genome activation, was absent in 2-cell cloned embryos when using enucleated interphase zygotes as recipients [99]. Further proof of this idea is supported by the observation that oocyte recipients at the germinal vesicle (GV) stage fail to develop after NT [84]. A possible contributing factor for the low developmental potential of enucleated GV oocytes and interphase zygotes is the low levels of maturation promoting factor (MPF) in these recipients (discussed below). Taken together, while the mechanism of reprogramming remains largely unknown, essential reprogramming factors are present in the recipient's cytoplasm during M phase, but absent during interphase, at least in the mouse model [99].

It is still possible that some unknown factors beneficial for reprogramming might be stably associated with chromatin and lost during enucleation. It is well known that spindle factors are associated with the

meiotic chromosomes, and therefore, enucleation could impair spindle function. Indeed, in human SCNT, it is apparently necessary to leave the recipient genome to achieve development to the blastocyst stage, at the cost of producing a triploid embryo [100]. How spindle function is affected by SCNT in livestock species will be discussed later in this entry.

Coordination of Donor and Recipient Cell Cycles

During a single cell cycle, a cell must double all of its components, segregate its genetic material equally to the two daughter cells, and undergo cell division. One exception occurs during the first few cell cycles of early embryo development where no net growth occurs. However, cell-cycle events associated with duplication and segregation of the nuclear DNA still occur. Another exception to the mitotic cell cycle is meiosis, which results in halving the chromosome number. Only germ cells undergo meiosis, while somatic cells only mitosis.

The mitotic cell cycle has four sequential phases: G_1, S, G_2, and M. During S phase (S for DNA synthesis), replication of DNA takes place. During M phase (M for *mitosis*), the cell divides all its components equally into two daughter cells. Cell growth occurs only during interphase, which constitutes G_1, S, and G_2. In a typical in vitro–cultured mammalian cell, interphase lasts about 23 hours (of a 24-hour cell cycle) while M phase is very short, lasting about one hour. S phase takes about half of the cell-cycle time (reviewed in [101]). The gap phases G_1 and G_2 are designed to provide extra time for the cell to grow and checkpoints for favorable growth conditions as well as for DNA damage.

At fertilization, the oocyte is arrested at MII, in a diploid state, while the sperm cell has completed meiosis and is haploid. Following oocyte activation by the sperm cell, the oocyte resumes meiosis to become haploid, thus matching the chromosome content and forming a viable diploid embryo. In NT, of course, it is not important that the donor chromosome content matches the recipient's since the oocyte chromatin is removed. Rather, the donor's cell-cycle phase should be compatible with the recipient cytoplasmic reprogramming content, which in turn depends on the recipient's cell-cycle phase. An important cytoplasmic reprogramming factor that has been extensively studied and has a profound effect on the donor nucleus is maturation promoting factor (MPF).

Campbell and colleagues, at the Roslin Institute (Scotland), carried out pioneer work in cell-cycle coordination between the donor cell (karyoplast) and recipient cytoplast prior to NT [16, 17, 102]. Their work suggests that cell-cycle coordination is a very important factor that should be taken into account prior to NT experiments to avoid damage of the donor chromatin.

For NT, mature MII cytoplasts are the recipients most frequently used. These contain high levels of MPF (also known as M-Cdk). MPF is a complex of two factors, protein kinase $p34^{cdc2}$ and cyclin B. MPF activity is regulated through synthesis and degradation of cyclin B and through phosphorylation of $p34^{cdc2}$. MPF activity is responsible for nuclear envelope breakdown (NEBD) and premature chromosome condensation (PCC) of the donor nucleus following activation of reconstructed embryos. MPF declines progressively after activation or fertilization and remains low during interphase. Declining MPF levels are followed by nuclear membrane reformation and DNA synthesis. NEBD and PCC occur independent of the cell-cycle stage of the donor nucleus in MII-arrested oocytes. In contrast, when activation precedes NT for a few hours, MPF activity is low and nuclear envelope integrity is maintained because NEBD and PCC do not occur.

An intact nuclear membrane prevents replication of previously replicated DNA [16, 103]. Transferring donor nuclei in S or G_2 phases into MII cytoplasts followed by activation leads to NEBD and eventually to DNA rereplication, likely resulting in ploidy abnormalities. In addition, PCC could also cause chromosomal damage of S-phase nuclear donors. These early observations suggested that only G_1 embryonic donor nuclei should be transferred into unactivated MII cytoplasts. In contrast to unactivated MII oocytes, activated oocytes serve as "universal recipients" since MPF activity is low and NEBD/PCC do not occur, allowing the transfer of any nuclear donor without the risk of DNA rereplication. In these reconstructed embryos, coordinated replication of nuclear DNA should occur. Indeed, unsynchronized sheep blastomere donors developed to the blastocyst stage more frequently when using activated cytoplasts (low MPF) compared with cytoplasts activated following NT (high MPF) [17].

For differentiated cells, however, activated oocytes might be poor recipients because NEBD and PCC are thought to be beneficial for reprogramming the donor nucleus. In bovine, for instance, when activated enucleated MII oocytes were used as recipients for somatic donors at different stages of the cell cycle (except S phase), development did not proceed to the 8-cell stage. However, unactivated MII oocyte recipients resulted in successful in vitro development to blastocyst [104]. Similarly, activated oocytes were shown in mice to be ineffective for development to term when using cumulus cells as donors [105]. These results suggest that activated oocytes, with low levels of MPF, fail to reprogram somatic donor nuclei. Blastomeres, on the other hand, probably require little or no reprogramming and thus can be cloned successfully with activated recipients as in Campbell et al. [17]. Not surprisingly, for somatic nuclei donors, the most common recipient is the unactivated enucleated MII oocyte.

Later research showed that donor genomes at G_0, G_1, and M phases of the cell cycle can be transferred into unactivated oocytes and produce offspring. For instance, embryonic stem (ES) cells arrested at metaphase produced live mice [106]. Metaphase-arrested chromatin donors are ready to segregate and form a pseudo-second polar body, thus eliminating the extra set of chromatin. However, G_2 donors were observed to fail at extruding the pseudo-second polar body resulting in tetraploidy [104], probably because they are "out of phase" with the meiotic cytoplast. This, combined with the rereplication event, could explain the consistent failure to produce viable offspring with G_2 donors (reviewed in [107]). For G_0 and G_1 donors, spindle function inhibitors are required to prevent pseudo-polar body formation and loss of chromosomes.

There is no apparent advantage between nuclei at G_0, G_1, or M phases for NT. Somatic cell donors are routinely synchronized at the G_0 phase of the cell cycle prior to NT. However, synchronized G_0 or G_1 fetal fibroblasts were compared and no clear superiority for either donor was found. Their relative cloning efficiencies were cell-line dependent in cattle [107]. Synchronization of ES cells at G_0 or G_1 might be problematic since they have a very short G_1 phase, and if induced to become quiescent (G_0), they likely differentiate. The most successful studies in cloning mice with ES cells used unsynchronized cell populations [108, 109], but others were less successful [110, 111]. ES cells at presumptive G_1 (by selecting small cells) were used with cloning success [112] and without success [113]. ES cells were also synchronized at M phase with moderate success in several occasions [106, 114, 115].

Taken together, enucleated MII oocytes seem to be the best recipients. However, the cell cycle of the donor nuclei might be less important since cloning success is achieved with G_0, G_1, and M donors, adapting the NT protocol accordingly.

Sources of Nuclear Donor Cells

Donor cells of different ages including embryonic, ES, fetal, and adult cells have been used for NT. It has been suggested that the age of an adult somatic donor cell could be transmitted to the clone. Such belief originated from a study showing that Dolly and other cloned sheep had shorter telomeres compared to age-matched controls [116]. The belief was later emphasized by the premature death of Dolly. However, several studies in cattle and mice showed that telomere length was normal in clones; telomerase activity was found to be reactivated in cloned bovine preimplantation embryos at similar levels to fertilized controls. Yet, further studies in sheep showed that indeed clones have shorter telomeres [117], suggesting that the mechanism of telomerase reactivation differs in this species. Nonetheless, studies have not observed premature aging in clones produced by SCNT.

Beyond age, a more interesting discussion relies on the epigenetic differences between donor cells. Differentiated somatic cell types diverge in their gene expression programs but have similar global chromatin configurations and modifications, or epigenomes. However, the epigenome of differentiated cells contrasts with that of undifferentiated pluripotent cells. It is probably the epigenome features that render one cell more amenable to reprogramming following NT rather than the cell's specific gene expression program.

Epigenomes Differentiated cells are different to pluripotent cells in several epigenetic features. Compared to pluripotent cells, differentiated cells show expansion of repressive domains marked by H3K9me3 and

H3K27me3 [118]. Similarly, differentiated cells show hypermethylated DNA compared to ES cells [119] and have lower levels of histone acetylation, consistent with heterochromatin configurations [120]. In agreement, electron microscopy showed that ES cells have dispersed global chromatin architecture, while the chromatin of the differentiated cells is more compact [121].

The epigenome of a differentiated cell can be reverted to that of an ES cell by overexpression of master-regulatory genes of pluripotency, thus forming iPS cells [19]. It has been shown that iPS and ES cells have similar global DNA methylation [20, 119] and similar global levels of the histone modifications H3K4me3, H3K9me3, and H3K27me3 [118, 119, 122].

Differentiated Versus Undifferentiated Donors It is generally postulated that an inverse relationship exists between the differentiated state of a donor cell and its "reprogrammability." This hypothesis is based on NT efficiencies obtained with different types of donor nuclei ranging in their differentiation status from the totipotent zygote to the terminally differentiated cell.

It has been suggested that a small proportion of somatic stem cells are present in a tissue sample, and these cells, rather than differentiated cells, account for the successful cases of SCNT. Studies were performed to test whether terminally differentiated cells are "clonable." First attempts to clone mice with donor lymphocyte cells failed [123]. Thus, a two-step NT procedure, in which ES cells are derived from cloned embryos and used for embryo tetraploid complementation, was later adopted for lymphocyte and olfactory neurons, resulting in viable mice offspring [124, 125]. Later on, cloned mice were produced by direct NT of T lymphocyte cells, albeit with a very low efficiency [126]. These results show that terminally differentiated cells can be cloned, but does not reject the possibility that less differentiated cells might be better donors.

In contrast to terminally differentiated cells, blastomeres give high frequencies of development after NT. Yet, the developmental potential of donor blastomeres decreases as the cleavage stage of the embryo increases. In mice, a gradual decline is observed from the 1- to the 4-cell-stage embryo followed by a steep decline from the 4- to the 8-cell stage, remaining low thereafter (reviewed in [127]). In cattle, such a significant decline in developmental potential is observed after the 8-cell stage (e.g., [13]). Apparently, the greatest decline in developmental potential after blastomere NT occurs following embryonic genome activation.

Literature reviews on NT generally support that ES cells are better than somatic cells in terms of the developmental potential of the reconstructed embryos. This view is based on experimental evidence gathered from a few early studies in mice, where good outcomes were achieved using ES cells as donors [108, 109, 112]. In these studies, the cloning efficiency (here defined as development to term after blastocyst transfer to surrogate females) ranges from 8% to 21%. These values are much higher than those obtained previously with SCNT by Wakayama and colleagues, where cloning efficiencies ranged from 0.4% to 1.6% using cumulus cells [128] and fibroblasts [129], respectively. Other studies also found similarly low mice cloning efficiencies (0–2.5%) with fibroblast cells (e.g., [130]).

However, lower efficiencies (0–5.4%) were also reported with ES cell donors (e.g., [111, 113–115]). These studies question whether ES cells have indeed better developmental potential than somatic cells following NT and suggest that major reviews are relying too heavily on positive results while overlooking the negative ones. In a critical review, Oback and Wells [127] argue that postimplantation sample sizes are generally small in animal cloning and thus insufficient to draw robust conclusions. Furthermore, they claim that many confounding factors exist in nuclear transfer experiments, rendering comparisons difficult. These factors include cell line and sex, confluency of donor cell culture, cell-cycle, passage number, and nuclear transfer procedure. Oback and Wells conclude that to determine whether ES cells have a better developmental potential than differentiated cells, it is necessary to carry out large NT experiments in which ES cells and the same cells induced to differentiate prior to NT are directly compared while keeping other parameters constant. Taken together, the published data are inconclusive but suggest that ES cells give better cloning efficiencies than somatic cells. Indeed, only one study directly compared the developmental potential of ES cells to somatic cells, resulting in a cloning efficiency of about four times greater with ES cells [112].

According to Jaenisch's group, the cloning efficiencies with ES cells are 10- to 20-fold higher than with somatic cells after embryo transfer [76]. These authors

have proposed that ES cells have better developmental potential following NT because they are undifferentiated and thus require less reprogramming than differentiated cells [76]. For instance, ES cells already express pluripotency-associated genes such as Oct4, Nanog, and Sox2, needed for early embryogenesis. In contrast, these genes need to be reactivated in differentiated cells. A second hypothesis could be that ES cells can be more easily reprogrammed as they have overall open chromatin configurations compared to differentiated cells, which typically have compact heterochromatin. The open and accessible chromatin of ES cells might facilitate the binding of nuclear remodeling factors found in the oocyte's cytoplasm.

Unfortunately, ES cells cannot be stably derived in livestock species yet. However, it is probably a matter of time until the mechanism and factors that govern pluripotency are discovered in these species. When derivation of ES cells in farm animals becomes possible, it would be of interest to further test their developmental potential compared to that of somatic cells following NT.

Differential Organelle Contribution

During fertilization, the oocyte and sperm each contribute a haploid set of chromosomes to form a diploid zygote. However, most of the cytoplasm and organelles are inherited from the oocyte. Among these are mitochondria, with their own genetic material. An exception to this is the centrosome, which is partly contributed by sperm. The differential contribution of the centrosome and mitochondria can affect NT outcomes. These contributions can be altered by the method used to transfer the donor chromatin.

Centrosome Inheritance The centrosome is the main microtubule-organizing center (MTOC) of animal cells involved, among other functions, in assembly of the mitotic spindle for cell division. This organelle is composed of two centrioles surrounded by abundant centrosomal proteins, which are often referred to as pericentriolar material (PCM). The centrosome is replicated during the S phase of the cell cycle from material stored in the cytoplasm. Mammalian oocytes have no centrioles but contain PCM that is recruited by the sperm centriole after fertilization, restoring a functional centrosome. Mice, however, are acentriolar until late preimplantation stages, achieving embryo cleavage by using maternal MTOCs.

In SCNT, the MTOCs associated with the oocyte meiotic spindle are removed while the centrosome from the donor cell is introduced [131]. It is not well understood the composition of the donor centrosome once within the recipient. Also, it is unclear whether the donor centrosome recruits leftover PCM from the recipient oocyte [131]. Nevertheless, it is thought that the donor centrosome needs to be remodeled into a zygotic centrosome for normal embryonic cleavage [131].

Centrosomes from donor cells at S phase might be reduplicated following oocyte activation in the subsequent S phase [132]. This would lead to the formation of extra spindles followed by aberrant segregation of chromosomes, a phenomenon frequently observed with S-phase donors. Even when using G_0 donors, 35% of bovine reconstructed embryos had abnormal cleavage correlated with abnormal centrosome number and distribution [133]. This suggests that providing only one centrosome does not guarantee normal centrosome function following NT.

An early NT study in monkeys suggested that removing the MII meiotic spindle depletes the oocyte of spindle proteins NuMA and HSET [134]. These proteins closely associate with maternal chromosomes and are required for mitotic spindle function. This study showed disorganized spindles with misaligned chromosomes in all reconstructed embryos, which were unable to produce pregnancies. However, in a later study using a different nuclear transfer procedure, NuMA location and spindle formation were normal in most reconstructed monkey embryos [135]. Taken together, these results suggest that different parameters of the NT procedure can affect centrosome function.

Mitochondrial Inheritance The mitochondrion is a special organelle, having a double membrane and containing its own genome (mtDNA). The main function of mitochondria is to produce energy in the form of ATP. Other functions include production of reactive oxygen species (ROS), calcium signaling, and apoptosis. mtDNA encodes for 13 mitochondrial proteins involved in ATP synthesis, for 22 tRNAs, and for

2 rRNA molecules involved in translating mitochondrial proteins [136]. Replication and expression of mtDNA are regulated by the nuclear genome through the expression of transcription and replication factors that translocate into mitochondria.

Mitochondria are maternally inherited because sperm mitochondria are targeted for destruction upon fertilization [137]. In SCNT, the donor cell mitochondria can persist and contribute to the reconstructed embryo, thus resulting in heteroplasmy (two different populations of mtDNA). Donor mitochondrial contribution is quite variable, ranging from 0% to 59% (reviewed in [138]). A bovine oocyte contains about 250,000 mitochondria, a 100-fold compared to a somatic cell [139]. Therefore, high heteroplasmy probably results from preferential amplification of donor mitochondria.

Compatibility between nuclear and the recipient's mtDNA seems to play an important role in SCNT. It has been shown that autologous SCNT (a female donor cell is transferred to its own enucleated oocyte) improves the frequency of pre- and postimplantation development when compared with heterologous SCNT [140]. Likewise, bovine reconstructed embryos developed more frequently as the similarity between the mtDNA haplotype of the donor and of the recipient cell increased [141]. Moreover, it is thought that the developmental block commonly observed in interspecies-SCNT embryos is due to genomic-mitochondrial incompatibilities [142].

Transfer of Donor Nuclei From the above discussion, it is apparent that the method chosen to deliver the donor chromatin into the cytoplast can have implications in terms of organelle inheritance of the reconstructed embryo. By whole-cell fusion, the donor cell contributes the nuclear and cytoplasmic material including mitochondria and centrosome, while nuclear microinjection does not. This would not seem to be problematic in mice since maternal MTOCs suffice to form the spindle-chromosome complex during cell division. In livestock species, however, centrioles function in spindle formation during early embryo cleavage. Nonetheless, pigs have been cloned by nuclear microinjection (e.g., [83]), suggesting that the presence of a centriole is not necessary for embryo cleavage in pigs. While cell fusion contributes mitochondria and cytoplasm, there is no evidence that either heteroplasmy or the amount of somatic cytoplasm contributed by a single donor cell is enough to reduce the developmental potential of the reconstructed embryo.

Cell fusion has been directly compared to nuclear microinjection in cloning experiments. In pigs and cattle, greater preimplantation development with the cell fusion method has been reported [143, 144]. Unless centrioles are often transferred along with residual cytoplasm during nuclear microinjection, these results suggest that centrioles are not strictly necessary for embryo cleavage, although their presence enhance preimplantation development. In mice, conflicting data have been reported when comparing the two methods. These mixed results are consistent with the exception that centrioles are dispensable in mice during preimplantation stages. Interestingly, it has been reported that the quality of blastocyst produced by cell fusion was better; analysis showed that piezo-assisted microinjection can cause DNA damage by shear forces [145].

Activation of Reconstructed Embryos

In mammals, egg activation is achieved when summation of intracellular Ca^{2+} oscillations reach a minimum threshold. Egg activation leading to Ca^{2+} oscillations is thought to be triggered by a sperm-specific isoform of PLC, known as PLC zeta (PLCζ), introduced into the oocyte following fertilization [146]. It has been suggested that summation of these Ca^{2+} oscillations encodes information for directing later development. For instance, few Ca^{2+} oscillations lead to decreased implantation, while excess Ca^{2+} oscillations, to increased postimplantation failure in mice [147].

Maturation promoting factor (MPF) also plays an important role in MII arrest and in regulating Ca^{2+} oscillations (reviewed in [148]). Inhibiting MPF activity enhances oocyte activation. Inhibition of protein synthesis (by cyclohexamide) or inhibition of phosphatases (by 6-dimethylaminopurine [6-DMAP]) can decrease the activity of MPF and induce meiotic progression. These inhibitors are usually combined with stimulation of Ca^{2+} oscillations to efficiently activate reconstructed embryos. However, it is important to bear in mind that these chemicals have broad spectrum actions and can interfere with other cellular processes [148].

In the absence of the natural inducer of egg activation, several artificial methods exist to trigger activation of reconstructed SCNT embryos, including electrical pulses, ethanol, calcium ionophore A23187, ionomycin, strontium, and thimerosal (Thi)/dithiothreitol (DTT). With the exceptions of strontium and Thi/DTT, the other treatments induce a single Ca^{2+} oscillation [149]. Comparisons of several activation methods in mice cloning could not found a preferred method [95].

To mimic more physiological activation events, sperm-mediated activation methods have been used. Fertilized oocytes were used as recipients, but such approach has not produced any significant improvement in developmental potential to term in mice or bovine cloning [150, 151]. To avoid the added complication of removing the sperm chromatin, an alternative activation protocol involved directly injecting the sperm activating factor PLCζ, in the form of mRNA, resulting in long-term Ca^{2+} oscillations [152]. This approach improved gene expression patterns of several genes and reprogramming of the repressive histone mark H3K27me3 [153]. Therefore, mimmicking sperm-activation events might improve reprogramming of the donor nucleus.

Another factor that can be controlled in activation protocols is the timing of activation following embryo reconstruction. It is common practice to delay activation for 1–3 h to extend the time for nuclear remodeling after nuclear envelope breakdown. This "nuclear exposure" has been shown to be beneficial in bovine [104]. However, the effectiveness of this approach likely varies between species since in monkeys, it was shown that development improves by immediate activation [154].

Culture of Reconstructed Embryos

For animal cloning, the reconstructed embryos can be directly transferred to a surrogate female or cultured in vitro to the blastocyst stage followed by transfer. Since in vitro culture functions as a first filter to select growing embryos with exclusion of the developmentally arrested ones, it allows transferring fewer embryos to surrogates and is, therefore, widely used. Many factors can be manipulated in an in vitro culture system to affect the developmental outcome of cloned embryos. These factors include incubation temperature, media composition and osmolarity, oxygen tension, culture substrate, communal or individual culture, embryo concentration, cocultures, medium renewal, and embryo stress. Analyzing each of these factors is outside the scope of this entry, but the reader is encouraged to read Vajta et al. [155] for a comprehensive review on embryo culture. Instead, an eccentric culture preference of cloned embryos will be highlighted.

Usually, NT experiments culture cloned embryos in conditions designed for normal embryos. However, as discussed during *nuclear reprogramming*, a cloned embryo is usually not a normal one. Several reports support that reconstructed embryos have altered metabolism and culture requirements compared to normal embryos (e.g., [77, 156]). For instance, due to incomplete reprogramming of the donor chromatin, mice cloned embryos produced with muscle nuclei overexpress the glucose transporter GLUT4 and thus exhibit enhanced rates of glucose uptake and benefit from somatic cell culture media instead of standard embryo culture media [77]. The benefits of using somatic cell culture media included improved blastocyst formation rate and increased total cell numbers in the resultant blastocysts. These results suggest that normal embryo culture conditions might subject cloned embryos to a harsh selection process, while somatic-like culture media seem to maintain the viability of reconstructed embryos, allowing them more time to complete nuclear reprogramming. Nonetheless, sequential use of different embryo culture media has been shown to dramatically improve blastocyst development of mice reconstructed embryos [156]. Taken together, culture media for reconstructed embryos should be optimized to match the donor cell preferences.

Perinatal/Neonatal Care

Once cloned blastocysts have been transferred to surrogate animals, work is usually limited to monitoring the progress of pregnant surrogates of livestock species. However, it is important to bear in mind that cloned animals are prone to suffer health problems arising from epigenetic errors caused by incomplete nuclear reprogramming of the donor chromatin. Respiratory difficulties seem to be the main problem in cloned

neonates. Other health problems include myoarthroskeletal malformations and metabolic abnormalities. It is advisable that cloned neonates are regarded as being at high risk [157], and thus, intensive care should be provided to increase survival. Some studies suggest that veterinary intervention during the perinatal and neonatal periods can improve the survival rates of cloned livestock animals (for a review, see [158]).

Perinatal care involves monitoring readiness for birth, induced parturition, and induction of final pulmonary maturation. For yet unclear reasons, pregnancies of cloned fetuses often extend beyond the normal gestation period [157]. While this might indicate that cloned fetuses require more time in utero to complete maturation, prolonged gestations are associated with increased birth weight, dystocia, and increased morbidity and mortality [157]. To prevent these problems, induction of parturition is commonly carried out. In parallel, to aid pulmonary maturation, pharmaceutical drugs are often administered to promote production of lung surfactant necessary for alveoli inflation. Due to respiratory deficiencies, cloned neonates can quickly become hypoxic and acidotic. Lack of vigor and weak suckling reflexes are other common symptoms of cloned neonates. Thus, intensive care of the cloned neonate is crucial, even for preventative measures. Good care practice includes providing oxygen for at least one hour, heat, mechanical ventilation for more severe cases, and monitoring blood parameters [158].

Improving Development

From the above discussion, it is clear that veterinary science can play an important role in the management of pregnancy and neonatal care to improve the survival rate of cloned animals. In the laboratory, researchers have attempted many things to improve cloning efficiencies. The two most promising areas that have yielded the best results are chromatin remodeling treatments and embryo aggregation.

Chromatin Remodeling Treatments

Relaxation of the donor chromatin could enhance the reprogramming of the donor nucleus. To this end, a few different approaches have been implemented to treat donor nuclei or SCNT embryos. Well-defined chemical treatments include trichostatin A (TSA) and 5-azacytidine (5-Aza).

Early in the mouse zygote, both parental genomes are rich in histone acetylations, suggesting that these epigenetic marks are important for reprogramming. Treatment of donor cells with TSA, a histone deacetylase inhibitor, has been used to increase histone acetylation and promote opening of the chromatin. Such treatment led to increased development to blastocyst stage in bovine [159]. Later on, optimized TSA treatments resulted in significant increases (up to tenfold) in development to term compared to untreated groups in mice cloning (e.g., [160]). Remodeling of the donor chromatin with TSA has been the single most important innovation for improving consistently the efficiency of SCNT [95, 161].

DNA methylation patterns have been observed to be abnormally high in cloned embryos [36], and therefore, some researchers have attempted to correct this epigenetic abnormality by treating the donor cells with 5-Aza, a DNA demethylating drug. Such treatment, however, has led to poor blastocyst development [159]. A similar decrease in developmental potential was also observed when using 5-Aza in cloned embryos at the 2-cell stage [162]. It is thought that such failure is due to the effects of 5-Aza on massive DNA demethylation and subsequent DNA rearrangements and formation of pronuclei [163]. Chromosomal abnormalities resulting from 5-Aza treatment would be consistent with the regulatory function of DNA methylation on chromosome stability. These unsuccessful results also suggest that following fertilization, active global demethylation of the sperm chromatin must be well regulated to prevent chromosomal damage. Indeed, the sperm genome retains some methylated regions including centromeres, which contribute to chromosomal stability. When 5-Aza and TSA are used together, however, a synergistic effect has been observed in cloned bovine preimplantation development compared to TSA treatment alone [164].

Another approach to induce chromatin relaxation involves using cell extracts from Xenopus eggs to treat differentiated donor cells prior to NT. The rationale is that many of the reprogramming factors present in the mammalian oocyte might also be present in the frog egg. This approach showed a significant increase in development to term in sheep [165]. Treated cells had lower global levels

of the heterochromatic epigenetic mark H3K9me3, thus probably contributing to more relaxed chromatin configurations and to improved cloning efficiencies.

Notoriously, somatic cells have even been preheated at nonphysiological temperatures prior to NT in order to relax higher order chromatin; however, development to term was not significantly higher than nontreated control [166].

Overall, when the "right" treatment is used (such as TSA), remodeling of donor chromatin appears to improve development of cloned embryos. A better understanding of chromatin remodeling following fertilization or NT might help design a "cocktail" of drugs to efficiently remodel the differentiated chromatin of somatic donor cells.

Embryo Aggregation

Two hypotheses exist supporting the rationale of embryo aggregation. One involves the *community effect* in which the ability of a cell to take a specific differentiation pathway is enhanced when more neighboring cells are differentiating in the same way [167]. Since cloned embryos tend to have lower cell numbers than fertilized controls, at least in mice [168], the *community effect* obtained by aggregation might enhance the formation of the ICM and/or TE lineage [169]. The second hypothesis involves *epigenetic embryo complementation* [168, 170]. While the aggregated embryos are genetically identical, reprogramming defects of one embryo can be compensated by another embryo, and vice versa. Although embryo complementation is largely unknown, it is thought that cell-cell communication between blastomeres, by permeable gap junctions or by autocrine and paracrine factors, compensates for deficiencies between blastomeres [170]. It is possible that both hypotheses work together since greater cell numbers will increase the opportunities for epigenetic embryo complementation.

Aggregation of four-cell cloned embryos improved developmental potential and gene expression. In mice, expression of Oct4 increased to normal levels, the number of cells was higher at the blastocyst stage, and development to term was increased eightfold compared to single-clone embryos [168]. In bovine, embryo aggregation resulted in blastocysts with double the number of cells and in upregulation of a subset of differentially expressed genes involved in transcription, biosynthesis, and signaling compared with single-clone embryos [170]. Overall, embryo aggregation is an interesting approach to improve the quality of a cloned blastocyst.

RNA interference

While this entry was in production, an article was published in which mice cloning efficiencies were increased tenfold and the gene expression of the resultant offspring was similar to IVF controls [171]. Such impressive outcome was simply achieved by knockdown of a single gene, Xist, by RNA interference. This study showed that cloned mouse embryos usually undergo permature overexpression of Xist as well as aberrant X chromosome inactivation. Although regulation of X chromosome inactivation differs between mammals [172], cloned bovine embryos were also observed to overexpress Xist [173]. Therefore, the next logical step would be to try the same Xist knockdown approach in livestock species.

Summary Points

- SCNT involves using a somatic donor nucleus and an enucleated oocyte to produce an animal genetically identical to the donor.
- The first NT experiments were carried out in 1928, the first successful SCNTs in the late 1950s, and the first cloned adult mammal (Dolly) in 1996.
- Basic research in the nuclear reprogramming mechanism following SCNT could yield transferable knowledge to produce iPS cells safer for regenerative medicine. Realistic pharmaceutical/agricultural applications of SCNT include production of transgenic animals and cloning prizewinning animals for breeding purposes.
- NT is commonly carried out with micromanipulators, although micromanipulator-free NT is possible and effective. NT steps include oocyte maturation, enucleation, nuclear transfer, fusion, activation, embryo culture, and embryo transfer.
- Common problems in SCNT include low cloning efficiencies and developmental abnormalities. The placenta is mostly affected by the technique.
- Problems in SCNT probably originate from incomplete reprogramming of the donor chromatin.

Faulty chromatin reprogramming in cloned embryos includes hypermethylated DNA and increased H3K9me3, especially in the TE.

- Gene expression reprogramming is usually aberrant in cloned embryos, with differences between species. Pluripotent genes often fail to be reactivated in mice, although reactivation is normal when ES cells are used as donors. Fewer markers exist to assess reprogramming of pluripotency and TE lineage in livestock species, and the existing data are rather conflicting. Imprinted genes are often deregulated and differentiation-associated genes incompletely silenced.
- MII oocytes are the best recipients as they have high MPF levels. Reprogramming factors are lost when enucleating interphase recipients, which also have low MPF levels.
- Donor nuclei can be in G_0, G_1, or M phase of the cell cycle. No specific cell type has been found to be advantageous for NT; however, inconclusive data suggest that ES cells are superior donors than somatic cells.
- Centrosomal structures are recovered by introduction of centrioles along with donor cell in livestock species, although normal spindle function is not always observed in reconstructed embryos.
- Increased compatibility between genomic DNA and mtDNA is beneficial for SCNT.
- In livestock species, cell fusion appears to result in better development than nuclear microinjection, consistent with centrosomal function recovery.
- There is no preferred method for oocyte activation.
- Normal embryo culture media are not optimal for reconstructed embryos.
- Cloned neonates are at high risk, and thus, intensive care should be provided to improve survival.
- Remodeling of the donor chromatin with TSA has been the single most successful innovation for improving consistently the efficiency of SCNT.
- Aggregation of cloned embryos seems to improve embryo quality by two working models: community effect and epigenetic embryo complementation.
- X chromosome inactivation appears to be deregulated in cloned embryos and correcting this by Xist knockdown can dramatically improve development.

Future Directions

Although efforts are being made toward dissecting the mechanism and the factors that bring about nuclear reprogramming of the donor chromatin, scientists are still quite far away from gaining a clear understanding. Even if there is general consensus that the low efficiency of SCNT originates from faulty nuclear reprogramming, there is no common agreement in where the bottleneck is. Does it lie in the reprogramming of the trophectodermal lineage or is the pluripotent lineage to blame? Is deregulation of imprinted genes the culprit of low cloning efficiencies or is it the incomplete silencing of differentiation-associated genes? Is incomplete remodeling of the overall chromatin structure preventing the SCNT technology from thriving? Does the bottleneck lie in the misregulation of X chromosome inactivation? Perhaps all these are contributing factors responsible for the low SCNT outcomes. Unless much further efforts are dedicated toward understanding the mechanism of nuclear reprogramming inside the oocyte, scientists will not have clear answers to such questions. The great improvement in cloning efficiencies observed with TSA treatment and Xist knockdown gives much hope and emphasizes that innovations can radically improve the technology.

In basic science, SCNT is not limited to nuclear reprogramming. For instance, SCNT interferes with centrosomal function in livestock species, and more research is needed to understand donor centrosome behavior, spindle formation, and embryo cleavage following NT in these species. SCNT can also provide insight into genomic-mitochondrial interactions, the effects of heteroplasmy, and preferential mitochondrial amplification. Such studies might warrant a change in technique such as the method by which the donor chromatin is delivered into the cytoplast.

As the science behind SCNT will be better understood through years of research, it is likely that the outcomes of this technology will closely match those of IVF. When that day comes, widespread use of SCNT technology in livestock species would be feasible. However, being an artificial reproductive technology, SCNT is surrounded by ethical issues and regulations that should be fully contemplated to ensure good use of the technology for the benefit of society.

By-catch In fisheries, species that are caught by accident and are discarded dead or alive but injured back into the ocean, a major threat to marine biodiversity.

Conservation medicine The emerging discipline of ecological health in practice.

Global toxification Global toxification can be referred as the deposition of thousands of environmental contaminants in the biosphere that are poorly degraded and can move through water, wind or other transport medium to other countries, regions or continents with catastrophic effects in individuals and populations.

Harmful algal bloom A rapid increase or accumulation in the population of toxic or otherwise harmful phytoplankton in an aquatic system. These events also are known as red tides due to the coloration of the bloom that varies from brown to red. Some examples of harmful toxins include brevetoxin, ciguatera, domoic acid, okadaic acid.

Hypoxia Deprived of adequate oxygen supply.

Invasive species "An invasive species is a nonnative species – including seeds, eggs, spores, or other propagules – whose introduction causes or is likely to cause economic harm, environmental harm, or harm to human health. The term *invasive;* is used for the most aggressive species. These species grow and reproduce rapidly, causing major disturbance to the areas in which they are present." (http://www.invasive.org/101/index.cfm).

Ornamental fisheries Ornamental fisheries is often used as a generic term to describe aquatic animals kept in the aquarium hobby, including fishes, invertebrates such as corals, crustaceans (e.g., crabs, hermit crabs, shrimps), mollusks (e.g., snails, clams, scallops), and also live rock.

Sentinel species Due to their size, movements and behavior, marine mammals, sea birds and sea turtles have been classified as sentinel species because they can provide essential early warning information of damage to the environment and consequently raise concerns for public health. These animal groups can serve as sentinels of marine ecosystem health in relatively pristine habitats or highly degraded or overfished ecosystems.

Taurine An essential sulfonic acid for muscle development in animal species.

Transdisciplinarity (TD) TD thinking employs perspectives and methods that transcend traditional disciplinary boundaries and engage students in addressing real-world problems. TD requires the team members to share roles and systematically cross discipline boundaries. The primary purpose of this approach is to pool and integrate the team expertise so that more efficient and comprehensive assessment and intervention may be provided in a determined field. The communication style in TD involves continuous give-and-take among all members on a regular, planned basis. Assessment, intervention, and evaluation are carried out jointly. TD brings together students, and outside the classroom, the future academic experts, field practitioners, community members, research scientists, political leaders, and business owners among others, to solve some of the pressing problems facing the world, from the local to the global and the natural and social sciences, to address the ecology and health of species and ecosystems.

Definition of the Subject

The ocean, in which life on earth began, is increasingly threatened by human activities. Ecological stresses – including overfishing, transformed coastlines, pollution, sediment loss, introduced species, emerging infectious diseases, altered agricultural runoff, sewage discharges, red tides, increased ultraviolet radiation, and an

apparently changing climate with acidification and increased hypoxia – are together impacting oceans and the health of humans, marine life and ecosystems. The health of the marine environment is at risk. Methods to assess marine ecosystem health are grossly lacking. A system to monitor and assess marine health threats linked to conservation and management policies is needed. This chapter summarizes the state of the oceans, human impacts including fisheries, climate change, globalization, trade, and coastal development, and provides solutions including an integrated health assessment initiative for marine ecosystems, the use of early warning indicator species, and day-to-day green activities that you as a citizen can contribute for a healthier planet.

Introduction

The global loss of biological diversity affects the well being of both animals and people. Human impact on ecosystems and ecological processes is well documented. Habitat destruction and species loss have led to ecosystem disruptions that include, among other impacts, the alteration of disease transmission patterns (i.e., emerging diseases), the accumulation of toxic pollutants, and the invasion of alien species and pathogens [1–3].

Beyond more visible terrestrial systems, growing evidence indicates that the ecological integrity of marine ecosystems is also under increasing threat. Oceanographers have been documenting changes in sea surface and deep core ocean temperatures, ocean acidification and increased hypoxia caused by human activities and global environmental change. The world coastal zones face enormous human developmental and urbanization pressures as most people on the planet live along the coast. Some ecological health symptoms of collective human impacts on the marine environment include increased frequency and intensity of harmful algal blooms (HABs) killing marine organisms. For example, brevetoxicosis in manatees, dolphins, and sea turtles; domoic acid poisoning in sea lions, cetaceans, and brown pelicans; ciguatera in Hawaiian monk seals and sea lions; and brown tide poisoning in humans; are being linked to increased environmental stress on species at higher trophic levels as a result of overfishing, loss of breeding/nursery habitats, and the spread of persistent chemical pollutants such as dioxins and PCBs that bio-accumulate in the food chain [2, 4–7]. Many populations of marine mammals, marine birds, and sea turtles are exposed to pollutants from agricultural runoff, human sewage, and pathogens with a terrestrial origin. Intensive agricultural practices resulting in increased nutrient loading and decreased water quality give rise to concerns of *Cryptosporidium* contaminations and potentially harmful algal blooms [8]. However, methodologies to assess marine ecosystem health are very poorly developed and the scale of monitoring required is well beyond present surveillance capacity. The health consequences of these events require innovative monitoring strategies in order to promote disease prevention, health management, and conservation. Society is ill-equipped to deal with these health impacts at present, lacking professionals with the transdisciplinary skills to link ecosystem, animal, human health issues, and inadequate large scale marine health surveillance capacity [9–11]. But these skills are necessary to change policy and management for improved health. For the past 30 years, human impacts on the health of the planet can be classified within four areas of environmental concern [12]:

1. Increasing biological impoverishment, including loss of biodiversity, habitat destruction and degradation, and modification of ecological processes.
2. Increasing global "toxification" including the spread of hazardous wastes and toxic substances and the impact of low level pollutants such as the pervasive endocrine disruptors.
3. Global environmental change.
4. Global transport of species, including but not limited to pathogens and parasites, into novel environments.

These discrete and cumulative human-induced global impacts have not only diminished the environmental capital of the planet but have also yielded an array of health concerns including the growing physiological impacts on species' reproductive health, developmental biology, and immune systems [13–15].

The Living Ocean

The ocean is the basic source for the hydrologic cycle that makes life on Earth possible, a global thermostat

that regulates entire climates, absorbs carbon dioxide and generates oxygen, a superhighway that carries most globalized trade; and, the playground for millions of people. The ocean comprises approximately 71% of the planet's surface with an area of about 361 million square kilometers (139,400,000 square miles). More than 50% of this area is over 3,000 m (9,800 ft) deep and a total volume of about 1,347,000,000 km^3 (322,280,000 cubic miles). Each cubic mile of seawater weighs 4.7 billion tons and holds 166 million tons of dissolved solids. One of the most unique aspects of ocean water is its salinity, or dissolved salt content. The measurement of salinity is essentially the determination of the amount of dissolved salts in 1 kg of water and is expressed in parts per thousand (‰). Ocean salinities commonly range from 33‰ to 38‰, with an average of 35‰. Six elements (chlorine, sodium, magnesium, sulfur, calcium, and potassium) constitute over 90% of the total salts dissolved in the ocean. The pressure in the ocean increases with depth due to the weight of the overlying water at the rate of 1 atm (=15 lb per square inch), for every 10 m (33 ft). The average temperature of the ocean is 3.9°C (39°F).

Over 230,000 marine species are known to science to date; however, the total could be up to 100–1,000 times that number. However, the extinction threat of marine species is increasing dramatically due to overexploitation and habitat loss. Climate change is becoming an important factor; due to shifting temperatures species ranges are expanding to the poles and into deeper, cooler waters. Shifts in currents and temperatures will affect the food supply of animals. To date, many species have suffered commercial and regional extinction. Entire coral reefs are getting lost within a single generation [16].

Recent studies demonstrate that viruses, despite their small size, are the most abundant biological entity in the ocean (see http://oceanworld.tamu.edu/resources/oceanography-book/microbialweb.htm). Scientists have identified less than 1% of the viruses on the planet; however, there can be three million viruses in 1 ml of water and each one contains 0.2 fg of carbon. That number is larger than the number of stars in the observable universe. Viruses consume the carbon equivalent to 200 million belugas (*Delphinapterus leucas*) if it is estimated that there are approximately 4×10^{30} viruses in the oceans worldwide [17, 18]. Using a molecular technique denominated "shotgun sequencing," Venter et al. (2004) reported 1,800 genomic species based on sequence relatedness, including 148 previously unknown bacterial phylotypes in water samples from the Sargasso Sea [19]. In total, over 1.2 million previously unknown genes were represented amongst these phylotypes and the vast majority of these unknowns have not yet been grown and studied.

Fish Diversity

Fish are the most species-rich class of vertebrates, numbering greater than 56,000 described species and subspecies, of which over 1,100 new species have been added since 2008, with these vertebrates adapted to a diverse range of aquatic habitats from desert to glacial mountain lakes and from deep sea vents to intertidal marshes [20]. Due to their relative abundance, fish and other aquatic animals have played a prominent role in human civilization by:

- Providing an important protein and omega-3 fatty acid source from both fisheries and aquaculture.
- Rapidly becoming one of the most common laboratory animal models for a variety of toxicological, infectious disease, immunologic, and genetic research facilities.
- Remaining the most numerous companion animals, as pets in bowls, aquariums, and ponds.
- Representing the fastest growing vertebrate taxa used for education in public displays at aquaria and zoos.
- Serving as vital sentinel species for marine and freshwater ecosystem evaluation, habitat assessment, conservation medicine, and ecological health.
- Being propagated for stocking natural fisheries for sport and natural enhancement.

Thus, an understanding of fish health and disease is crucial to incorporate a proactive approach when addressing current and future needs in conservation medicine and ecological health. Invertebrate animals will be discussed in brief in this chapter, but have an equally significant role in conservation medicine. Historic and current examples will be used to better illustrate these conservation medicine dilemmas and challenges.

Fisheries, Habitat Destruction and Extinction

Over 30 years ago, it was assumed that the future of humanity was going to be in the ocean due to its magnificent biodiversity and huge biomass, but within three decades humankind has been able to cause severe impacts to a degree that the ocean is in trouble due to ocean acidification, climate change, and overfishing. The ocean provides a primary source (16%) of animal protein (fish) and more than 3.5 billion people depend directly of fish resources. Approximately 110 million tons of fish are removed every year – an amount way above carrying capacity of the ocean – with a value of $50 billion dollars. For example, along the Gulf of Mexico, 5 kg (12 lb) of sea life mostly juvenile fish may be killed for 0.5 kg (1.1 lb) of shrimp. Basically, more than 75% of world fish stocks assessed for several years are over-exploited or depleted from which 60–70% require urgent action (i.e., allow recovery by closing a fisheries). Marine food webs are literally being fished down causing a cascade of trophic effects unknown to human and ecosystem health [21]. These fisheries core problems can be summarized as follows: there are too many fishing fleets with massive government subsidies for fishermen and cooperatives, with millions of tons of unwanted bycatch picturing an unsustainable future for fisheries. Entire fish stocks can be depleted within a single fishing season. Commercial fishing operations target unregulated deep waters where large migratory fish predatory species are exploited with their bycatch consequences. Of course unreliable statistics (i.e., how many fish of a species swim in the ocean and how many can be caught without causing a decline) and habitat destruction including nurseries, coral reefs, and sea floors are major contributing factors.

Recent numbers estimate that less than 1% of marine habitats are protected. Although more than 50,000 species are estimated to live in a coral reef, only the extinction of four snails, five seabirds, and four marine mammals is known in the history of humankind. These numbers provide a sense of how little is known about the ocean [22].

Aquaculture

Although aquatic organisms have been cultivated for centuries, aquaculture production is a relatively new branch of agriculture. US aquaculture in 2008 has decreased slightly from previous peaks in tonnage (2004) and in value (2006), while world aquaculture production for inland and marine animal species has nearly doubled in both tonnage and value from 1998 to 2007 [23]. With an increase in aquaculture production, there are also increased pressures on wild fisheries to help provide broodstock, seedstock, and a nutritional source of protein and fish oils in commercial aquaculture feeds for raising many aquatic species of economic importance. A frequently cited example that well illustrates realized and theoretical pressures on these fisheries is that the ecologic input purported to raise caged salmon in Norway roughly equates to 5 metric tons of food fish to produce each metric ton of farmed salmon [24]. Despite these numbers being calculated over two decades ago, opponents to commercial salmon aquaculture most frequently cite them. Even when dietary inputs for commercial salmon feeds are not double counted for fish meal and for fish oil components, and when increased feed efficiency is noted, the best true feed conversion rates of dry weight to wet weight (1.6–1.8) still require fishery inputs for salmon aquaculture [25]. In 2000, it was recognized that despite dependence on wild fisheries for fishmeal in aquaculture, aquaculture production actually increased world fish supplies, but this earlier publication does not account for a doubling of production since 2000 [26]. Based on increases in feed conversion efficiency for a variety of aquaculture species and scientific improvements in nutrition, some researchers are convinced that aquaculture use of wild fisheries for fish meal and fish oil in aquaculture feeds will continue to decrease [27]; despite an encouraging decrease in use of wild fisheries to all farmed aquaculture of 0.63 and fisheries harvest for fishmeal in aquaculture feeds are well-regulated, others debate that greater economic and regulatory efforts are still needed to protect wild fisheries [28]. One of the greatest limiting factors when rearing marine piscivorous species for food consumption is the need for taurine in the diets for these animals [29]. Taurine is commonly found in fishmeal but often is lacking in soy and poultry replacements. In the US, the Food and Drug Administration (FDA) restricts supplementing taurine to commercial aquaculture diets, which prevents more sustainable dietary formulations for some of the most popularly raised and

consumed fish species and provides a significant hurdle for US offshore aquaculture development.

One of the greatest areas of growth in aquaculture has been the shrimp industry in Central and South America and Southeast Asia. FAO reports show industry growth from 5 million metric tons in 1995, to 40 million tons by 2007 [23], which suggests the reason shrimp are considered "white gold" *oro blanco* in countries such as Ecuador. Problems with such rapid expansion and increasing global demands include habitat use, species protection, and infectious disease. As early as the 1970s in Thailand, shrimp was becoming the fastest growing aquaculture industry, and environmental impacts realized by 1995 were mangrove/wetland destruction, saltwater intrusion, land subsidence, water quality degradation, sediment disposal, abandoned shrimp farms, and displacement of traditional livelihoods [30]. Similar environmental issues including fishery depletion were associated with the shrimp industry in Honduras over a similar time period [31]. Infectious disease problems resulted in major production declines in Taiwan (1988), for China (1993), in Thailand (1996–1997), for Indonesia and the Philippines (1999), and in Ecuador (1999) [32, 33].

The effects of aquaculture on fisheries are multifactorial, including: habitat modification, using wild seed for stocking, impacts on food web interactions, introduction of non-indigenous organisms, and effluent discharge [26]. Understanding the basics for aquaculture health management, biosecurity, and biodiversity are vital to addressing needs of ecological health for aquatic organisms. Aquaculture's effects on biodiversity are seldom recognized as a positive benefit. Instead, aquaculture is viewed as negatively impacting biodiversity through land use, fossil fuel reliance, environmental pollution, antibiotic runoff, exotic species introductions, reliance on fish meal from wild fisheries, broodstock or seed allocation, and water use. However, maintaining biodiversity is essential for current and future aquaculture development [34, 35]. Some realized and potential positive impacts of aquaculture on biodiversity include decreasing exploitation on wild seafood products with cultured livestock, using certain species to enhance wild stocks, and increasing natural production and species diversity [35].

With any type of live organism captive management, there is naturally a direct relationship with disease and production level. As the intensity of production increases, the prevalence of disease also tends to increase. Intensification generally refers to increasing the number of animals raised in confined or restricted areas. For example, the greatest limitations to sustaining development of Asian aquaculture – which accounts for 89% of world aquaculture production [23] – are aquatic animal health concerns, and, without appropriate aquatic animal health management, major disease outbreaks and newly emerging pathogens will continue to dominate costs and socioeconomic development of aquaculture throughout Asia [36].

With optimal aquatic organism health management, advances in technology can be better applied for disease prevention, diagnosis, and amelioration. Increased sophistication of fish health research, advances in molecular diagnostics, and improvements in fish health management will minimize infectious disease in aquaculture (e.g., vaccines and biosecurity) similar to trends noted in production of some terrestrial animals. For example, infectious disease has appeared to have declined in the Atlantic salmon aquaculture industry in British Columbia today than it was 15–20 years ago (Dr. Gary Marty, personal communication).

Aquaculture poses great potential to help feed world populations, improve human health through nutrition, and advance agricultural practices through more practical environmental solutions [37]. As aquatic health practitioners, incorporating a strong foundational aquatic animal health program is essential to the management and future success of aquaculture and the maintenance or restoration of our aquatic ecosystems (including wild fisheries).

Fisheries Interactions

Rapid alterations to the ocean are creating a medium for new disease patterns and health manifestations. For example, new variants of *Vibrio cholerae* have been identified within red tide algal blooms. These toxic blooms are occurring in greater frequency and size throughout the temperate coastal zones of the world.

Intensive aquaculture is a relatively new agricultural practice, and there are several interactions between aquaculture reared animals and wild fisheries. Intensive aquaculture is marked by decreasing needs for natural

inputs for husbandry in order to raise greater biomass (number of fish) in less space, while extensive aquaculture relies on enhancing natural food resources and has a greater dependence on livestock density. In the context of conservation, some prominent concerns are fisheries interactions resulting in disease outbreaks, farm-source antibiotic/chemical resistant pathogens, and environmental contamination caused by effluent. Although aquaculture may contribute to these fisheries interactions, other industries and environmental utilization also make substantial changes to the environment posing a threat to aquaculture and native fish populations. Because of the vast expanse of oceans identifying and quantifying the impact of infectious disease on wild fisheries is compounded by fish mortalities going undetected through natural attrition by predation, sinking to the bottom, or occurrences in remote locations. Understanding infectious diseases in wild fish requires effectively led transdisciplinary teams with expertise in fisheries biology, medicine, pathology, mathematical modeling, and ecology. By including participation of concerned citizens and multiple specialists, fish health professionals will be ultimately equipped to diagnose, treat, and/or mitigate emerging infectious disease outbreaks in fisheries and aquaculture [38].

Emerging Infectious Diseases

Emerging infectious diseases are commonly defined as those that have newly appeared in a population or have existed but are rapidly increasing in incidence or geographic range or appear in new hosts (i.e., canine distemper a disease of dogs has killed tens of thousands of common seals in the North Sea [10]). This rapid trend has been observed in many human populations from AIDS to SARS and from West Nile virus infection to highly pathogenic H5N1 avian influenza. Although current diagnostic methodologies allow the detection of novel pathogens, unprecedented number of emerging and reemerging diseases in marine ecosystems such as brucellosis in dolphins, aspergillosis in coral reefs, fibropapillomatosis in sea turtles, toxoplasmosis in sea otters, and morbillivirus infections linked to large-scale marine mammal die-offs have been documented in recent times [39]. The trends of diseases in the oceans are increasing since 1970 for many taxa including turtles, corals, urchins, and mollusks [40]. The human impacts on the world's oceans have devastated populations, species, and ecosystems at a rapid scale. Some of the emerging pathogens recently documented in the oceans are listed in Table 1. Ancient diseases like mycobacteriosis (tuberculosis) offers some of the greatest health management challenges for managed collections or groups of fish, and have been identified recently in hundreds of freshwater and marine ornamentals, laboratory animals, and also from aquaculture reared striped bass (*Morone saxatilis*) from California [41]. In the last decade mycobacteria infections have been isolated from clinically infected wild striped bass and in juvenile Atlantic menhaden (*Brevoortia tyrannus*) disease prevalence ranged from 2% to 57% in tributaries of the Chesapeake Bay [42] and multiple *Mycobacteria* spp. can colonize numerous species of native fish in this region [43].

Aquatic Invasive Species

Invasive species have a great socioeconomic impact when they negatively impact native species [44]. These alterations can be associated with directly changing the environment such as by eating prey species of fish or invertebrates, eating or disrupting the vegetation and/or phytoplankton, eliminating other important native controls for insects or pests, and changing water flow and water chemistry [45]. Many of these examples can be found on the website for the aquatic nuisance species task force [46]. Some of these examples include (invasive species – probable source):

- Nile perch (*Lates niloticus*), Nile tilapia (*Oreochromis niloticus*), and Water hyacinth (*Eichhornia crassipes*) in Lake Victoria, Africa – developmental projects [47].
- Asian carp in Mississippi Delta and Great Lakes, United States – aquaculture/research.
- *Hydrilla verticillata* in southeast US and *Caulerpa taxifolia* in the Mediterranean – aquarium and water garden trade.
- Zebra mussels (*Dreissena polymorpha*) in watersheds around the world affecting native shellfish populations, water quality, and larval fish – ballast water [48].
- Sea lamprey (*Petromyzon marinus*) parasitism and disease in Great Lakes fishery – possibly Erie and Welland canal projects.

Living Ocean, An Evolving Oxymoron. Table 1 Some emerging and reemerging disease agents recently reported in the marine environment

Disease	Species	Etiologic agent
Adenovirus infection	Walrus	Walrus adenovirus W77R
Arboviral encephalitis	Orca, gray whales, harbor seal [130]	EEE, SLE viruses
Aspergillosis	Marine organisms	*Aspergillus fumigatus*
Black band /white band disease	Corals	Unknown
Bonamiasis	*Ostreaedulis*	*Bonamia ostrea*
Brucellosis in marine mammals	Marine mammals	*Brucella ceti, B. pinnipedialis*
Calicivirus infections	Marine mammals	Caliciviruses (39 serotypes)
Candidiasis	Marine mammals	*Candida albicans*
Canine distemper	Phocids	Canine distemper virus
Chlamydiosis	Sea turtles, Pinnipeds	*Chamydophila psittaci*
Cutaneous viral papilloma	Orca, manatees	Papillomavirus
Disseminated neoplasia/Germinomas	Bivalves	Unknown
Dolphin morbillivirus	*Stenella*	Dolphin morbillivirus
Enterovirus infection	Walrus	Walrus enterovirus 7–19
Erysipelas	Delphinids, little blue penguins [131]	*Erisipelotrix rusiopathiae*
Fibropapillomatosis	Marine turtles	Unknown: Herpesvirus, Retrovirus, possibly Papillomavirus
Hepadnaviral hepatitis	Delphinids	Hepadnavirus
Herpesvirus infection	Phocids; northern fur seals; salmonids, ictalurids, *Cyprinus carpio* [132], *Sardinops sagax*, other fish species	Phocine herpesvirus 1 and 2; Marine herpesvirus 206 CyHV1,2,3; HPV1,2; CCV; Pilchard herpes virus
Immunoblastic malignant lymphoma	*Stenella/Tursiops*	Unknown
Ichthyophoniasis	*Oncorhynchus* spp. [133]	*Ichthyophonus* sp.
Leptospirosis	Pinnipeds	*Leptospira* spp.
Keloidalblastomycosis/ Lobomycosis/Lobo's disease	Delphinids	*Lacazia loboi*
Melioidosis	Delphinids (SE Asia, Australia)	*Burkholderia pseudomallei (Pseudomonas pseudomallei)*
Megalocytisvirus	Numerous fish species [134]	BCIV, ISKNV, RSIV, TRBIV
Metastatic oral squamous cell carcinoma	Delphinids	Possibly papillomavirus
Morbillivirus infection	Mediterranean monk seals	Monk seal morbillivirus

Living Ocean, An Evolving Oxymoron. Table 1 (Continued)

Disease	Species	Etiologic agent
Mycobacteriosis	striped bass; ornamental and tropical marine and freshwater fish species	*Mycobacterium* spp.
Native parasitic sea lice	Salmonid species of genus *Onchorynchus* [135, 136]	*Lepeophtheirus salmonis*
Nocardiosis	Marine mammals	*Nocardia* spp.
Phaeohyphomycosis	Temperate marine teleosts	*Exophiala* spp.
Phocine distemper	Phocids	Phocine distemper virus
Polyps and hyperplasms	Corals	Unknown
Porpoise morbillivirus infection	Porpoises	Porpoise morbillivirus
Pseudomoniasis	Marine mammals	*Pseudomonas* spp
Ranavirus	Amphibians, fish, and chelonian species	FRV-3, numerous others
Rotavirus infection	California sea lion	California sea lion rotavirus A111R
Retrovirus infection	Walrus	Walrus retrovirus T2/19
Salmon fluke	*Salmonid* spp.	*Gyrodactylus salaris Malmberg, 1957*
Salmonellosis	Ornamental freshwater fish and dwarf African frogs	*Salmonella paratyphimyrium* and *S. typhimyrium*
Sea lion transitional cell carcinoma	California sea lions	Herpesvirus??
Seal influenza	Phocids	Influenza virus type A
Seal pox	Pinnipeds	Pox virus
Stress-related necrosis	Corals	High water temperatures
Toxoplasmosis	Pinnipeds, Delphinids	*Toxoplasma gondii*
Vibriosis	Marine mammals, fish, and shellfish [103]	*Campylobacter* spp., *Vibrio* spp., *Photbacterium* ssp.
Viral hemorrhagic septicemia	Marine and freshwater teleosts in northern hemisphere [137]	Viral hemorrhagic Septicemia virus (VHSV)
Whirling disease	Salmonid spp.	*Myxobolus cerebralis*

Invasive species are also detrimental because they *change* predator/prey ecology for ecosystems. These include species that are both predators and prey. Invasive predatory species have an obvious detrimental effect by preying on species that may not have had natural predators in certain habitats. Invasive prey species can have direct or more cryptic effects by consuming resources for native prey species, or through replacing a more nutritious food resource for predators. Some examples are:

Predatory Species

- Pacific Batfish (*Platax orbicularus*) in Molasses Reef in the Florida Keys 2000.
- Lionfish (*Pterois volitans, Pterois miles*) in Northwestern Atlantic and Caribbean, 1992 aquarium escape after hurricane Andrew Biscayne bay [49].
- Snakehead (*Channa argus*), in 2002, this species was discovered in a pond in Crofton, Maryland individual release from aquarium or live food industry.

- Butterfly (*Cichla ocellaris*) and speckled peacock bass (*Cichla temensis*) in Florida by intentional release as game fish 1984.
- Northern Pike (*Esox lucius*) in Davis Lake, California by individual introduction 1994 Prey Species.
- Alewife/Shad (*Alosa pseudoharengus*) 1931 in Great Lakes via Wellend canal.

A greater issue is caused by the release of animals from other geographical locations. Some of these animals may be closely related to native animals separated only by ecological barriers. These species can readily survive in the new location, but given the circumstance for release could pose a greater risk to native relatives. Some examples of this include the release of Maryland diamondback terrapins (*Malaclemys terrapin*) in New York waters from Asian food markets (personal communication with Russell Burke). These terrapins have been exposed to a variety of chelonian species from around the world in poor husbandry conditions that are often unregulated and unhygienic. These animals have potential to become asymptomatic or symptomatic carriers for new diseases that could pose a threat to native threatened and endangered populations. Some examples of sources for these invasives include:

- Aquaculture.
- Live Food Markets.
- Laboratories.
- Collectors.
- Water Gardens/Landscape designers.
- Unwanted Pets – Habitatitude™: (http://www.habitattitude.net/).
- Restoration/Repopulation projects.

New diseases and health problems in native populations can arise from invasives from all the descriptions above. Alterations in the environment can create poor water quality conditions for native species. Well-documented diseases associated with introductions of nonnatives have occurred in fish, invertebrates, reptiles, and amphibians:

- Chytridiomycosis by *Batrachochytrium dendrobatidis* – amphibians globally [50].
- Thiamin deficiency and thiaminase – salmonids Great lakes, alligators Lake Griffin, Florida [51, 52].
- Viral Hemorrhagic Septicemia VHSV – FW and possibly Marine from Great Lakes [53].
- *Hydrilla verticillata*/blue green algae – Avian Vacuolar Myelinopathy Southeastern US [54]
- *Myxobolus cerebralis* causing Whirling Disease Western US [55].
- *Gyrodactylus salaris* from Baltic to North Sea 1974 [56].
- Malpeque and MSX: links between disease and non-indigenous species in *Atla*ntic Canada [57].
- *Trypanosoma acerinae* from Caspian to Lake Superior in Ballast Water 1992 fish pathogen [58]. *Bonamia ostrea* from California to France, Maine, Washington State, and British Columbia [59–62].

As veterinarians and aquatic animal professionals, our role with aquatic invasives is to recognize new and emerging disease threats, including those that might be caused by human actions [63]. This role includes using our skills in education, nutrition, infectious diseases, and public health to help investigate problems associated with the current epidemic of aquatic invasive species. Some of these diseases may have been overlooked because of poor associations or because current husbandry complicate diagnosing new pathogens. Some brief examples of potential threats include:

- *Exophiala* sp. in cold marine and temperate water fishes [64].
- Megalocytisvirus in ornamental freshwater and marine fishes [65].
- *Salmonella* sp. in freshwater fish, amphibians, and turtles [66].
- *Enterococcus* sp. in sea turtles (Innis, Sims, and Weber unpublished data).

Ornamental Fisheries

Marine and freshwater ornamental fisheries are a growing area, and they involve largely unregulated movement of livestock with global implications for potential disease outbreaks [67, 68]. The ornamental aquarium industry includes captive (>90%) and wild freshwater fish with over 632 million animals produced in Malaysia alone as recorded by the Malaysian ornamental fish industry (2010), coupled with a far greater variety of marine ornamental species that are traded

with estimates of close to 8,000 different species of marine animals with only ~25 species captive bred [69–71]. FAO estimates in 2009 suggest 59% of all production of ornamental aquaculture related products were produced in Asian countries. Aquatic animals include fish, reptiles, amphibians, invertebrates (including corals), and live rock (dead coral that becomes encrusted with marine macro- and microorganisms in the wild). Farms in Florida (USA) and Southeast Asia raise many freshwater ornamental varieties with additional inputs from other countries, hobbyists, and wild-caught fisheries. Hobby specialty groups actively trade some of the animals highly prized for appearance, such as African and South American cichlids. The freshwater temperate ornamental industry consists primarily of koi (*Cyprinus carpio*) and goldfish (*Carassius auratus auratus*) with major production in Israel, Arkansas (USA), Japan, and China. There is little marine ornamental production of farm raised stock, and the majority of marine fish for the hobbyist trade come from captured wild stocks in the Caribbean Ocean, Red Sea, and Indo-Pacific Ocean. Methods used for collection in the Philippines for many marine species in the past have included dynamite stunning and potassium cyanide poisoning causing irreparable damage to stock collected as well as the environment and animals caught as bycatch [72]. Zoos and aquariums contribute to these pressures on aquatic animals; they are net consumers of wildlife and are and must maintain high standards of animal care. The increased fishing pressures on these animals have made some species extremely vulnerable. In just the last decade Banggai cardinal fish (*Pterapogon kauderni*) have become one of the first marine ornamentals to be listed on the International Union for Conservation of Nature (IUCN) red list for threatened species [73, 74], and institutions like the Shedd Aquarium in Chicago have sponsored conservation efforts such as *Project Seahorse* to help with education and research of dwindling numbers of sygnathid species. Although restoration projects are proposed to support conservation for many of these species [75], such endeavors can cause catastrophic effects on native populations, and will need to include aquatic animal veterinarians and fish health professionals to develop responsible protocols to help ensure the health status of captive breeding animals and their offspring prior to release with native populations. Restoration efforts should also involve conducting health surveys on wild populations to screen for presence of common and emerging pathogens known to threaten these native organisms [70].

The primary cause of mortality for many ornamental species is from stress associated with transport, resulting in death either immediately from environmental quality issues or later from disease. Mortality for wild caught ornamentals approaches 100% of some shipments. Shipments bring animals together from different geographical locations into holding systems with shared filtration. Geographical strains of common parasites can be deadly for naïve animals using a shared recirculating water source. Emerging infectious disease agents are largely undetected and seldom appear in the peer-reviewed scientific literature despite the existence of a large industry. This lack of knowledge is mostly the result of mortalities in the aquarium and ornamental trade being discarded without any obligation or regulation for movement of these animals, and often, no gross pathology and/or histopathology is performed on fish mortalities.

Threats to Coral Reefs

Destruction of coral reefs and coral diseases are fast outpacing new reef formation [76]. Coral reefs have tremendous species diversity and there are many new resources on conserving coral reefs. Expertise in understanding coral reef destruction through scientific research has uncovered numerous new pathogens and disease syndromes identified in corals, linking environmental quality and climate change to many problems faced by these invertebrates [77]. Corals are being threatened by anthropogenic (human-induced) and environmental variables such as bleaching, infectious disease, climate change, predator plagues, and invasive species [78]. Recently sunscreen was implicated in contributing to causing coral bleaching and promoting viral infections in heavily touristy areas [79].

Global Toxification

Pollution is a common thread for many of these environmental variables and several examples will be highlighted to illustrate the complicated nature of these

interactions. Natural populations of fish in Europe are contaminated with PCBs. Fish from the Rhone River downstream from an incineration plant had high levels of contamination, and that the consequence of this exposure was significant increase in cytochrome P-450 dependent monooxygenase activities [80]. Pollutants can have direct environmental consequences such as the accumulation of halogenated contaminants in farmed salmon, trout, tilapia, pangasius, and shrimp as compared with wild caught marine fisheries, showing salmon as having a greater contaminant level than all other species investigated and Polychlorinated biphenyls (PCBs) being found in the highest concentration [81]. Subsequent studies investigating salmon from Europe and North America in 2004 and 2005 suggested that PCB levels were also significantly higher than levels found in wild Alaskan Chinook salmon but that farms from Eastern Canada had decreased PCB detection in the second year [82–84]. Comparing over 2 metric tons of farmed and wild salmon from around the world for organochlorine contaminants, farmed salmon had significantly higher contaminant levels than wild salmon with Europe having higher levels than both North and South America [85]. However, more recent research showed that much of these differences were a result of lower lipid content in wild Pacific salmon than in farmed Atlantic salmon [86]. Pollutant levels in wild populations of salmonids from the Great Lakes may be improving based on human studies illustrating a decrease of PCBs and DDT among all populations in the Great Lakes region including sport fishers over a 10 year period from 1995 to 2005 [87].

Pollution is also evident from manmade causes and disasters from mines, factories, inadequate wastewater treatment, and oil spills. Fish exposed chronically to petroleum hydrocarbons at the site of the Exxon Valdez oil spill in Alaska had a significant difference in the prevalence and intensity of trichodina parasitism between sculpin originating from an oil-free and an oil-contaminated site, with the oil-contaminated having the greater infection; although extensive environmental differences in both sites were not sufficiently described, as this parasite can also increase rapidly in water temperatures differing by only a couple of degrees C°, especially in eutrophic conditions [88]. After exposure to a variety of pollutants, heavy metals, acid rain, and xenobiotics were shown to cause gross and microscopic lesions of the gill epithelium that were directly linked to osmoregulatory, acid–base, or hemodynamic malfunction, suggesting that toxins may be processed in the gills of fish similar to human pathways found in the kidney, intestine, and liver [89, 90]. Other investigators looking for biomarkers of toxicity caused by crude oil have demonstrated that even at very low exposure the metabolic enzymes citrate synthase and lactate dehydrogenase measured in the gills of Atlantic salmon appeared to be good biomarkers of exposure to the WAF of Bass Strait crude oil, and to chemically dispersed crude oil [90]. Among the many toxins in the aquatic environment, heavy metal toxins are of historical significance. Minamata disease is a disease in humans marked by severe congenital birth deformities that result from eating fish contaminated with methyl mercury waste first characterized in Minamata bay, Japan. Lakes in the Western US such as the Great Salt Lake are reported to have heavy concentrations of mercury and selenium affecting migrating waterfowl [91]. Trends in mercury concentrations in the US Great Lakes from 1969 to 2005 had the greatest downward trends in fish samples from 1969 to 1987, correlating to decreased mercury in sediment and peat cores over that period [92], marking positive news for mitigation of the bioaccumulation of this toxin in this region. Emerging chemicals of concern (ECC) are constantly being investigated such as the effect of endocrine disruptors on fish species [93]. In UK Rivers, a high prevalence of intersexuality and sexual disruption in the roach *Rutilus rutilus* was concomitant with environmental detectable levels of pollutant endocrine disruptors, documenting an initial change in vertebrate behavior related to such compounds [94]. Similar research is investigating fish endocrine disruption in rivers of Virginia and West Virginia.

Veterinarians and the medical profession have the ability to directly mitigate a growing pollutant problem of this century, antibiotics found in the aquatic environment and their possible link to antibiotic resistance of some pathogenic bacteria. Researchers are only beginning to understand the ramifications of antibiotic waste for various ecosystems generated from human and agricultural uses. With improved analytical techniques, antibiotics can easily be identified in waste water and post treatment effluent, and studies suggest that of six antibiotics (ciprofloxacin,

trimethoprim/sulphamethoxazole, tetracycline, ampicillin, trimethoprim, and erythromycin) tested pre- and post-wastewater treatment, some bacteria were resistant to all six antibiotics pretreatment, and posttreatment bacteria were still resistant to two of this antibiotics [95]. In broader surveys conducted on samples from 16 sites in the southern North-Rhine Westphalia of Germany, antibiotics were detected in all watersheds. Both large (Rhine River) and small creeks had some substances (erythromycin and sulfamethoxazole) identified in nearly all samples, and concentrations of these pharmaceutical products ranged from detectable to the limit quantization [96]. Early surveys in Germany also detected antibiotics in groundwater and wastewater, but groundwater in heavy livestock areas was free from antibiotic residues, suggesting that most environmental contamination in Germany is from human medical practices [97]. Although much of this environmental contamination is from human waste or terrestrial agricultural effluent, aquaculture may also contribute the problem of antimicrobial resistance. In a more comprehensive review of the literature, many veterinary treatments are found in the aquatic environment including insecticides, antihelmenthics, and antibiotics [98, 99]. Four Danish freshwater trout farms were investigated comparing inlet and outlet water samples, and assessing levels of antibiotic resistance from bacterial sampling of fish, water, and sediment. Two major fish pathogens (88 *Flavobacterium psychrophilum* isolates and 134 *Yersinia ruckeri* isolates) and 313 motile *Aeromonas* isolates had increased antibiotic-resistant among the culturable microflora that was statistically significant among the motile aeromonads; the study used five MICs from antibiotics commonly used in Danish aquaculture (oxolinic acid (OXA) and sulfadiazine-trimethoprim (S-T), amoxicillin (AMX), oxytetracycline (OTC), and florfenicol (FLO) [100]. In another study, Oxytetracycline-resistant (OTr) mesophilic aeromonads from untreated hospital effluent and from fish farm hatchery tanks in Cumbria shared tetracycline resistance-encoding plasmids identical to a similar plasmid found in *E. coli* even though coming from distinct locations [101]. The long-term consequences of antibiotic resistance in the environment are not fully understood, although some of the work by Costanzo showed certain antibiotics negatively affected bio-nitrification [95]. There are large research gaps for understanding all the implications of antibiotic pollution for ecosystem health and sources of these therapeutants, but this lack of research should not prevent further assessment and proactive approaches to addressing environmental accumulation with these drugs.

Microbes also cause environmental concerns for cultivated and harvested fisheries. Many of these pathogens not only cause disease in aquatic animals, but also pose a health risk for people. Some of the more recent findings include epidemiologic investigations of *Salmonella* outbreaks in Australia. One outbreak was the first to link gastroenteritis outbreaks in humans with identical isolates from home aquaria for multidrug-resistant *S. paratyphi* B dT+ (ApCmSmSpSuTc phenotype) (ampicillin, chloramphenicol, streptomycin, spectinomycin, sulfonamides, tetracycline) containing SGI1 [66]. Subsequent investigations correlated human outbreaks of gastroenteritis with a second multidrug-resistant *S.paratyphi* B biovar Java (*S. Java*) with strains that were resistant to ApCmSmSpSuTc, and this isolate was directly linked with home aquaria maintenance [102]. Aquaculture products can also become incidental vehicles to transmit pathogens as illustrated by a 1991 outbreak of cholera in Guayaquil, Ecuador of multiple antimicrobial resistant *V. cholerae* O1 recovered from a pooled sample of a bivalve mollusk and from 68% of stool samples from case patients [103].

Global Environmental Change

Climate change whether induced by humans or natural, has potential to greatly alter the aquatic landscape in ways poorly appreciated or understood by researchers at present. Climate change may be intimately linked to many issues presented in this chapter from providing sustainable aquaculture to harvesting ornamental fish, from the success or failure of invasive species [104] to natural changes in range for many animals, and from coral reef survival to the ecology of infectious disease organisms [78, 105]. Fish populations at risk to climate change in Northern European countries include disease threats from disease agents occurring in warmer climates such as *Lactococcus garvieae* in farmed trout in the UK [106] and proliferative kidney disease (PKD) in wild Swiss grayling (*Thymallus thymallus*) [107]. Aquatic

biologists and veterinarians must begin to keep records and develop methods of monitoring disease outbreaks in wild fisheries and in managed species globally.

Tracking Marine Disturbance and Disease in Marine Ecosystems

A new model of bridging the growing gap between conservation science and conservation advocacy that now faces the environmental movement is needed. Environmental problems are being defined as more complex interactions. The scale and complexity of issues require novel solution-oriented approaches that are based upon meaningful collaborations among disciplines and institutions. Obviously, the scale of the Ocean makes it difficult to get a handle on the entire health status of this marine environment. And certainly any focal subset of the Pacific Ocean for example the Bering Sea or the Hawaiian Islands does not diminish issues of scale. The ocean is huge by any measure.

An integrated assessment that links together data from ecological, climatic and economic sources was proposed in the late 1990s [108]. This project had the objective of identifying major marine ecological disturbances (MMEDs) through this assessment process. MMEDs can be mapped, using a geographic information system (GIS), to find spatial "hotspots" and temporal clusters of events (e.g., during El Niño years). Data for this effort is derived from peer-reviewed scientific articles, a network of government and academic researchers, existing data sets and, for more current events, mass media sources.

This ocean health framework is similar to traditional epidemiological (population health) models. The model tracks potentially harmful algae, marine pathogens, and other species that respond rapidly to environmental change. Diseases arise from a combination of pathogenicity (degree of disease causing capability), host vulnerability, and a conducive environment. Marine morbidity and mortality (disease) events may be symptomatic of compounding and chronic ecosystem abuse.

A comprehensive survey of instances of marine ecological disturbance, and a methodology for future major marine ecological disturbance (MMED) investigation, is desired by international, federal and state agencies in their efforts to better understand the changes occurring in the world's oceans. The HEED approach drew together the expertise of over 15 separate disciplines, organized historic data in one standard format, assessed the integrity and coverage of data, and provided a method for future standardized data collection and analysis. Events within this morbidity and mortality database served as (eco) indicators of ecologically and economically significant disturbances. The overall framework enabled the assessment of marine ecosystem health.

The six data sets integrated into the HEED (http://heedmd.org/) model include:

- MMED Database: Morbidity/mortality and adverse occurrences among coral, seagrasses, invertebrates, fish, sea turtles, sea birds, marine mammals, and humans, including HABs data.
- Climate Databases: Sea-surface temperature anomalies, precipitation anomalies, unusual weather events, movement of the Gulf Stream, and indices of climatological anomalies, including the NAO and ENSO phenomena.
- Biophysical Databases: Dissolved inorganic and organic nutrients, river flux, metal concentrations, water column stratification, oxygen, salinity, solar radiation, presence/absence and abundance of sentinel species.
- Baseline Ecosystem Datasets: Chlorophyll biomass, plankton abundance and diversity, dynamics and life history for benthic and pelagic species, and their organization in trophodynamic guilds for particular places over time.
- Economic Database: National Marine Fisheries Service fisheries statistics, Federal Emergency Management Agency and Small Business Administration requests for assistance, and other economic and social costs of morbidity and mortality events.
- Mass Media Database: Article searches of MMED-related stories and economic costs, to ensure complete coverage of data too recent to appear in published literature. Case studies include global marine mammal reports.

In HEED study areas which included the Western North Atlantic, Caribbean Sea, and the Gulf of Mexico, major marine ecological disturbances have increased during the last 50 years. Initial findings in the Atlantic Ocean show a rise in marine-related diseases along the USA Atlantic coast, Gulf of Mexico and Caribbean.

This suggests that coastal conditions conducive to illness are widespread. Other findings of note include:

- New diseases are emerging and old diseases are reappearing across a wide range of marine life.
- Humans face increasing health risks associated with seafood consumption and recreation.
- Of deepest concern, infections appear to be spreading among seagrass meadows and coral reefs, the habitat upon which other species depend.
- Disease outbreaks can lead to significant economic losses for seafood industries, fishing communities, trade, travel and tourism.
- Monitoring and supporting communication networks for harmful algal blooms, and combining disease and environmental surveillance, can generate health early warning systems.
- A continuation of the trends described could significantly alter the structure and function of coastal marine ecosystems.

Results from the original HEED effort for the Atlantic Ocean [109] depict a geographic expansion and overall increase in marine ecological disturbances over the last several decades – including unprecedented events, and disturbances of increasing severity. These have had, in some cases, significant human health and economic impacts. Increased understanding of marine ecological disturbances through the use of the tracking methodology provides a justification and basis for a rapid response to public health risks and threats to ecosystems. NOAA's Office of Global Programs and NASA provided support for the Atlantic Ocean monitoring effort (http://www.heedmd.org/).

Hawaiian Monk Seals as Sentinels of Ocean Health

Possibly the best indicator of ecological integrity of Hawaii's regional marine ecosystem, including the Northwestern Hawaiian Islands (NWHI), is the health of marine vertebrates known to be sensitive to system-wide human impacts including fishing. Sea turtles, sea birds, and marine mammals recently have been described as "sentinels" of marine ecosystem health [110, 111]. Hawaiian monk seals (*Monachus schauinslandi*) fall into this category. The Hawaiian monk seal is one of the most endangered marine mammals in the world and the most endangered pinniped in USA waters. Of three species globally, the Caribbean monk seal (*M. tropicallis*) is believed extinct since the late 1950s and the Mediterranean monk (*M. monachus*) seal nearly so with only a few hundred animals remaining. The decline of both species mirrored the development in their respective regions, including increasingly intensive fishing and degradation of coral reef ecosystems [112].

Populations of Hawaiian monk seals have shown a severe decline in recent years and have placed the species in threat of extinction comprising 1,300 individuals in the wild. Although little is known of the pattern of historic decline of the species, precipitous decline in juvenile survival of Hawaiian monk seals since 1990 followed a climate-induced shift in ecosystem carrying capacity together with overharvesting of lobsters, a known prey of juvenile seals. Monk seal-fishing interactions have been documented in all NWHI fisheries. It is highly likely that the cumulative effects of commercial fishing activity negatively impact the monk seal population through both direct and indirect (ecosystem level) mechanisms. It is unlikely this can be determined definitively unless observed by allowing commercial fishing to continue in or adjacent to monk seal habitat [112].

Understanding the potential role of disease and toxins in this recent decline is a high priority. Several natural sources of mortality have been identified or suggested (e.g., ciguatera poisoning, starvation, shark predation, trauma/mobbing and parasites), but the relative significance of these factors and their effect on population trends are poorly understood. Efforts to enhance the recovery of the Hawaiian monk seal will require a better understanding of the health and disease status of the wild population. Thus, health and disease impacts on the population merit a cohesive, well-supported effort to mitigate potential effects [113].

As demonstrated by intensive serologic surveys on a wide number of marine mammal species, it is evident that many diseases known to affect terrestrial species for decades or centuries are now recently being identified in marine ecosystems. Species and disease interactions are resulting in the appearance of mass mortalities and new reservoir hosts in new geographic areas. Examples of these diseases in marine ecosystems include several strains of morbillivirus, *Brucella* spp.

and leptospirosis. NMFS Marine Mammal Research Program has actively investigated Hawaiian monk seal health and disease for more than 30 years. This investigation has included surveillance and analysis, primarily in the Northwestern Hawaiian Islands (NWHI). Veterinarians, marine biologists and other scientists conduct studies including gross necropsy and histopathology, parasitology, hematology, serology, morphometrics, microbiology, epidemiology, scat and spew analysis, population abundance/survival assessment, and reproductive rates. Recent research [114] shows the serologic presence of several infectious agents. The three infectious diseases endemic to the MHI considered to have the highest risk for the Hawaiian monk seal population are morbilliviruses (i.e., canine distemper, seal distemper), *Brucella* spp. and *Leptospira* spp. Fortunately, canine distemper in Hawaii is rarely diagnosed in domestic pets. Leptospirosis is endemic and widespread but public awareness and state monitoring are helpful. Also, Hawaiian monk seals are mostly solitary, reducing the potential for the spread of this deadly disease from seal to seal. The potential for *Brucella* to affect the survival of Hawaiian monk seals is unclear but a cause for concern. *Brucella* is believed to cause reproductive failure in other species and techniques for diagnosis in monk seals are being developed and may be available in the near future.

Data collected regarding morbillivirus, *Leptospira* spp. and *Brucella* spp. need to be analyzed to provide for example: epidemiological trends, morbidity/mortality curves, geographic distribution and prevalence/incidence information. In addition, herpesvirus epidemics and morbillivirus serologic evidence are being reported affecting pinnipeds in the Pacific coast of the USA (http://www.pifsc.noaa.gov/psd/mmrp/health.php). A cooperative initiative has been proposed to systematically address these disease concerns in one of the richest ecosystems of the world.

Sea Turtles as Sentinels of Ocean Health

Habitat destruction, ingestion of plastics, fisheries bycatch, boat collisions, and emerging diseases are among the documented threats to sea turtles in all oceans. Because sea turtles are large and long-lived air-breathing animals that regularly visit the same sites near the coast, they are excellent indicators or sentinels of the health of an ecosystem.

Sea turtles have been threatened by an epidemic of fibropapillomatosis (FP – tumors of skin involving epidermis, dermis and other epithelial tissues) since the mid 1980s. These debilitating tumors are suspected of having a viral etiology. Populations of turtles exposed to agricultural runoff, pollution, HABs or warm water temperatures have been shown to have an increased risk of infection.

FP is a disease characterized by multiple cutaneous masses ranging from 0.1 to more than 30 cm in diameter that has primarily affected green turtles (*Chelonia mydas*), although the condition has been observed in other species including loggerhead (*Caretta caretta*), olive ridley (*Lepidochelys olivacea*), Kemp's ridley (*L. kempii*) and flatback (*Natator depressus*) turtles. The disease has a worldwide circumtropical distribution and has been observed in all major oceans. Where present, prevalence of the disease varies among locations, ranging from as low as 1% to as high as 90%. Although several viruses have been identified associated with the tumors, including several herpesviruses, a retrovirus and a papillomavirus, the primary etiological agent remains to be isolated and identified.

The green turtle nesting population, found at French Frigate Shoals, NWHI, has increased since its protection 18 years ago. No population impacts caused by FP have been observed in the number of nesting females, with the highest season ever being recorded in 1997 (ca. 500 nests); however, less than 100 nests were recorded for 1998. A photograph taken in Kaneohe Bay in 1958 documented the first case of FP for the Hawaiian Islands. This turtle was released to the wild. Between 1989 and 1997, 581 green turtles were captured alive at this Bay. Mild to severe FP was reported in 44% of the turtles handled, of which 17% presented oral tumors. The annual prevalence of the disease has ranged from 42% to 65% with no consistent trend observed. Growth rates for turtles with severe FP were significantly slower than turtles free of FP (1.0 vs. 2.2 cm/year carapace length). To date, FP has not been shown as causing a big impact on the overall population. However, further research is necessary to elucidate the long-term impacts. FP in green turtles has served as an indicator of ocean health at several levels. Although reported since the late 1930s in Florida, it was not until the late 1980s that it reached epizootic

proportions in several sea turtle populations. Long-term studies have shown that pelagic turtles recruiting to near shore environments are free of the disease. After exposure to these benthic ecosystems, FP manifests itself with primary growths in the corner of the eyes spreading to other epithelial tissues. Field observations support that the prevalence of the disease is associated with heavily polluted coastal areas, areas of high human density, agricultural runoff, and/or biotoxin-producing algae. Marine turtles can serve as excellent sentinels of ecosystem health in these benthic environments. FP can possibly be used as an indicator but correlations with physical and chemical characteristics of water and other factors need to be made [115]. Further research in identifying the etiologic agent and its association with other environmental variables can provide sufficient parameters to measure the health of coastal marine ecosystems, which serve not only as ecotourism spots but also as primary feeding areas for sea turtles.

One Ocean, One Health

The idea of the combined health of people, wildlife, and ecosystems – one health – is emerging from this increasingly apparent but still largely overlooked web of linkages. Symptoms of marine ecosystem distress due to nutrient loading with potential contributions of anthropogenic global climate change are associated with the frequency and intensity of HABs and associated toxicity for marine mammals and humans. Many populations of marine animals, marine birds, and sea turtles are exposed to pollutants from agricultural runoff, human sewage, and pathogens of terrestrial origin best described as pathogen pollution [116]. The following example involving a penguin, a pilchard, and a herpesvirus depicts how the terrestrial and aquatic environments are so delicately interconnected.

The Australian pilchard (*Sardinops sagax*) is a schooling fish related to herring that navigates temperate waters in Australia and New Zealand. Australia is also the range for the smallest and more primitive species of penguin referred to as the little blue or fairy penguin (*Eudyptula minor*) which inhabits the beaches of Western Victoria, Australia, Tasmania, and New Zealand. Although they can swim for long distances, *E. minor* do not exhibit the long migrations of Antarctic species. These penguins main food source is the pilchard. A great mass mortality of pilchard with epithelial lesions of the gills that greatly compromised respiratory and osmotic regulation was documented during 1995 off Western Australia. The spread of disease mortality for these animals was 30 km day^{-1} and after a thorough diagnostic investigation, one consistent finding was the presence of novel herpesvirus inclusions in the gills of infected pilchard [117]. The initial introduction of this herpesvirus is currently unknown. Shortly after, little blue penguins on Phillip and St. Kilda islands began experiencing great mortality of adult (86%) and first year birds (14%) with starvation and intestinal parasitism as the only consistent necropsy finding among 1,926 animals [118]. During the subsequent breeding season 1995–1996 these same birds delayed nesting season by 2 weeks and had a decreased chick fledged rate of 0.3 as compared with the mean of 1.0, and researchers concluded increased mortality and subsequent decreased reproduction were associated with the pilchard mortality [118]. Although the origin of the herpes virus is unknown, this example may very well exhibit the devastating consequences of novel pathogens and/or disease-translocation across geographic boundaries can have on multiple trophic levels [119].

Your Everyday Green Choices

Estimates show that marine litter is now 60–80% plastic, and that amount can reach 90% in certain areas. Plastic degrades slowly. Estimates for plastic bag degradation range from 500 to 1,000 years or even longer. Plastic pieces outnumber sea life 6:1 and there are expansive "garbage patches" of broken up plastics in both the Pacific and Atlantic Oceans (see http://marinedebris.noaa.gov/info/patch.html).

- Do your bit to minimize your impact on ocean pollution. Always remember the 3 Rs: Reduce, Reuse and Recycle. *Know what you are buying and how to recycle!!*
- Be a wise consumer. Support companies that are environmentally conscious. Buy products that minimize use of plastic or use degradable materials.
- Consumers choosing to buy sustainably sourced seafood and avoiding threatened species, i.e., Sea Food Watch App for smart phones.

- Follow the National seafood and sushi watch cards or consumer choice cards.
- Put pressure on governments and regulatory bodies to limit fishing subsidies and tighten regulations on industrial, agricultural and domestic pollution.
- Support research projects aimed at understanding pollution better and finding ways to reduce the amount of pollution in our oceans.
- Help support the establishment and expansion of Marine Protection Areas (MPAs). Presently, 1% of the oceans are MPAs.

Future Directions

Not all changes in fisheries can be simply ascribed to overfishing or environmental destruction; for example, the non-recovery of Pacific herring populations in Alaska has recently been attributed to natural mortality events caused by several infectious pathogens and subsequent disease, which has been illustrated using an age-structured assessment (ASA) model of disease and population abundance [120]. Box 1 illustrates how research advances when mitigating invasive and emerging pathogens such as *Myxobolus cerebralis* that causes whirling disease in many native species of salmonid fish. With the advent and increasing use of molecular diagnostics, infectious disease modeling, increasing globalization, and changing environmental conditions, marine health scientists will have to rely more heavily on epidemiology irrespective of specialty for the benefit of their clients as well as their patients. This chapter is far from comprehensive, but hopefully it serves to encourage readers, and especially our young readers, to think outside of routine way of life and to become involved with issues that demand a rapid response from consumption to recycling, from advocacy to policy change. Given the vast number of species and current exploitation of our aquatic resources many conservation issues have not been included but are equally relevant to conservation of the ocean, such as the exploitation of sharks and rays in finning fisheries,

Box 1. Whirling Disease: Problems and Solutions

Though speculative, the myxozoan parasite *Myxobolus cerebralis*, likely reached North America in the 1950s with frozen rainbow trout or imported brown trout from Europe [55, 121]. The first recorded epizootic in North America was among brook trout at a hatchery in Pennsylvania, USA. Subsequent episodes were reported in numerous other eastern state trout hatcheries, frequently among rainbow trout, one of the more susceptible species of salmonids [55]. Under conditions of high infectivity, whirling disease may induce severe cranial and spinal deformations and death as parasite stages feed upon and destroy skeletal cartilage prior to bone formation in young fish [122]. The myxospore stages of *M. cerebralis* in the skeletal elements of chronically infected trout may not result in the blackened tail and erratic swimming characteristic of acute disease. If the spores are not detected, the parasite will spread to new geographic regions with the transport of hatchery fish for stocking in rivers and streams for the sport fishery. This mode of parasite movement has facilitated the spread of the parasite to over 25 states in the USA, including most profoundly wild trout in the intermountain west (e.g., Colorado, Montana) where large scale population declines, particularly among rainbow trout have destroyed once highly prized sport fisheries [123, 124]. The two-host life cycle of *M. cerebralis*, which also includes the oligochaete *Tubifex tubifex*, has added to the complexity associated with the control and management of whirling disease. However, a combination of improved diagnostic procedures for parasite detection, in both fish and oligochaetes, and new management procedures in aquaculture are improving the ability to control whirling disease. The advent and now widespread application of PCR can detect the pathogen among fish with no clinical signs of disease, thus preventing the inadvertent movement of infected fish [125]. Improved sanitation in trout hatcheries using both treatments of the water supply with ultraviolet irradiation and several common disinfectants for ponds and equipment including transport vehicles has further reduced the spread of the parasite [126, 127]. Finally, the discovery and exploitation of rainbow trout strains resistant to whirling disease has provided a powerful

management approach to significantly reducing and perhaps eliminating whirling disease from certain hatchery environments and ideally from selected wild trout sport fisheries [128, 129]. The most broadly exploited whirling disease resistant rainbow trout strain is the product of 120 years of selection in a commercial hatchery in Europe. This strain is now being reared in state and commercial fish hatcheries in the USA. It is also being bred with wild trout with the aim to restore selected wild populations of rainbow trout in Colorado.

Terminal stage of *Myxobulus cerebralis* found in salmonid fish

Rainbow trout 2.5 mo post infection showing darker and deformed tail, deformed gill covers and cranium – inability to swim and eat lead to death.

Histopathology section stained with H & E showing trophozoites actively destroying cartilage in the young trout skeleton.

A rainbow trout with chronic deformities caused by whirling disease with a corresponding right lateral radiograph illustrating spinal and skull deformities.

invertebrate aquaculture production, and coral reef conservation.

The conservation of biodiversity in the ocean is becoming increasingly complex because of the intimate role that water has with conserving our terrestrial environs. The vastness of the aquatic world should not be looked at with trepidation, but rather with

excitement for the vast wealth of knowledge it has yet to bestow on us. Although the challenges presented are great, the ocean has been forgiving to anthropogenic transgressions and there is a need to continue striving to leave a smaller wake and help others follow by example.

Acknowledgments

E.P. Weber III wants to thank Dr. Bryon Jacoby for all his patience during the drafting, rewriting, and editing of this chapter and he thanks Dr. Ronald Hedrick for assistance with the whirling disease section and providing images. Dr Hedrick has led Fish Health at the University of California School of Veterinary Medicine in Davis over the last 30 years and has contributed to nearly 300 publications related to Aquatic Animal Health. Ron is a great friend, colleague, and mentor. We are most grateful to H.M. Smith, S. Sgroi and M. DeRario for their thoughtful input and comments for lightening it our scientific jargon up to an enjoyable reading for our K-12 public.

Root lodging Lodging resulting from failure of the anchorage system.

Stem failure moment Stem strength at the point of failure. Also described as stem strength.

Stem lodging Lodging resulting from buckling of the lower stems.

Definition of the Subject

Lodging is the process by which the shoots of small grained cereals are permanently displaced from their vertical stance. Lodging limits yield potential and reduces grower profits, but it is difficult to control because it is a complex process that is influenced by many factors including wind, rain, topography, soil type, previous crop, crop management, and disease. Significant progress was made during the 1950s, 1960s, and 1970s to reduce lodging risk by the introduction of semi-dwarf varieties. The reduced lodging risk of these shorter varieties enabled them to respond to greater amounts of fertilizers and this was a significant reason for the steady improvement in global cereal grain yields starting in the late 1960s. However lodging is still a major problem in many countries and there is an urgent need to improve lodging resistance to further increase the yield of cereal species.

Introduction

Lodging is the permanent displacement of cereal stems from their vertical position (Fig. 1) and usually only occurs after the ear or panicle has emerged. This can reduce yield by up to 80% and causes several knock-on effects including reduced grain quality, greater drying costs, and slower harvest. It is a problem that limits cereal productivity in both developed and developing countries.

Lodging Resistance in Cereals. Figure 1
Lodging in wheat

Lodging is a complicated phenomenon that is influenced by many factors including wind, rain, topography, soil type, previous crop, husbandry, and disease. It is frequently associated with conditions that promote plant growth such as an abundant supply of nutrients. Significant progress was made during the 1950s, 1960s, and 1970s to reduce lodging risk by the introduction of semi-dwarf varieties. These shorter varieties had a greater lodging resistance and could respond to greater amounts of fertilizers. For these reasons the introduction of semi-dwarf varieties was one of the most significant reasons for the steady improvement in grain yields starting in the late 1960s, which has resulted in cereal yields increasing by as much as 1 t ha^{-1} per decade in western Europe and 0.5 t ha^{-1} in many American and Asian countries [1]. The continued improvement in yields in some countries has been significantly aided by the use of plant growth regulators (PGRs) that further reduce crop height making cereals even more resistant to lodging. Four major types of PGRs have been introduced including chlormequat chloride during the mid-1960s, ethephon during the late 1980s, trinexapac-ethyl during the mid-1990s, and prohexadione-calcium in the 2000s. In France, Germany, and the UK, which have among the highest cereal yields in the world, PGRs are now applied to more than 70% of wheat area (W. Rademacher 2004, personal communication).

Dwarfing genes and PGRs have been very effective tools for reducing lodging risk and maintaining steady improvements in yield. However, they have not eradicated lodging and there is evidence that farmers will not be able to rely on these tools for further reductions in lodging risk in order to counter the escalating lodging risk resulting from continued yield increases. Several studies have shown that yield is reduced when crops are shortened too much [2–7]. The reduction in yield appears to be exacerbated by high temperatures or drought stress. Several of these studies indicate that the minimum crop height for optimum yield lies between 0.7 m and 1.0 m. Many modern varieties are already within this height range. While there is scope for further shortening with PGRs through sequential applications, pressure may be brought to bear to reduce their use because some PGRs leave residues in the grain [8]. It is therefore clear that new methods of improving lodging resistance in cereals must be developed.

During the 1990s and 2000s collaborative studies by biologists and engineers have elucidated the mechanisms of lodging in cereals [9]. Crucially it has been demonstrated that lodging may occur by two mechanisms: stem lodging and root lodging. These studies have culminated in models of the lodging process which help to understand how the plant interacts with its environment during the lodging process and identifies the most important plant traits that must be targeted to improve lodging resistance. Several studies have also explained how variety, sowing date, seed rate, nitrogen fertilizer, and PGRs affect lodging. This improved understanding offers the prospect of designing a lodging proof ideotype for cereals which may be achieved through a combination of crop management and plant breeding. This entry on lodging resistance in cereals describes (1) the impact that lodging in different cereal species has on crop yield and grain quality, (2) the mechanisms of the lodging process, (3) the effect of cultivar choice and crop management on lodging resistance, and (4) prospects for improving lodging resistance. This entry is intended to be a concise summary of the most important aspects of lodging resistance in cereals, and for a more comprehensive review readers are directed to Berry et al. [10].

Impact of Lodging on Grain Yield and Quality

Grain Yield

Lodging can reduce cereal yield by reducing the grain size and number or through reducing the amount of crop that can be recovered at harvest. This section deals only with physiological reductions in yield associated with lodging. The greatest lodging-induced reductions in grain yield occur when crops are lodged flat at anthesis or early on in grain filling. Yield reductions from this type of lodging have been reported to reduce yields of wheat by [11] 31–80% [12], barley by 28–65% [13–15], oats by 37% [16], and rice by 38% [17]. All of the above studies, apart from Easson et al. [12], artificially lodged the plants. This was achieved by growing the plants through wire netting and then moving the wires to effect lodging. This method has the advantage of lodging the crops at specific dates and at different angles, but may induce damage not normally incurred with natural lodging. Easson et al. [12] compared the yields of crops grown at high seed rate, which lodged naturally, with those at low seed rate, which experienced negligible lodging.

Smaller yield losses have been observed when the angle of lodging is less than 90° from the vertical. Lodging at 45° causes between one quarter and one half of the yield losses incurred from 80° lodging in wheat [18], barley [14], and oats [16]. Smaller yield losses also occur when lodging occurs at a later stage of development. Artificial lodging at the ear emergence, milk, soft dough, and hard dough stages reduced yield by 31%, 25%, 20%, and 12%, respectively [11]. Stapper and Fischer [19] supported these observations by showing that about 0.5% of the potential yield was lost for each day of the grain filling period that a crop was lodged flat. Crops that lodge before anthesis often have smaller yield losses than crops that lodge soon after anthesis [18]. This appears to be associated with the upper one of two internodes bending upward to partially re-erect the crop. Crops that lodge after anthesis have completed stem extension and are unable to re-erect themselves. In natural situations, the re-erected crops are very unstable and are usually re-lodged by unexceptional weather conditions [12].

Grain Quality

Artificial lodging has been observed to cause significant reductions in grain quality in terms of the bread making quality (measured as the Hagberg falling number [HFN]), individual grain weight, and the specific weight of the grain [10]. Lodging increases the likelihood of grain sprouting in the ear due to the more moist environment (Fig. 2) and this reduces HFN. Lodging induced during early grain filling reduced grain quality by reducing the HFN from 289 s to 114 s, reducing individual grain weight from 42.2 mg to 37.2 mg, and reducing specific weight from 70.3 kg/hl to 65.8 kg/hl. Lodging after early grain filling caused smaller effects on quality. A HFN of at least 250 s is required to produce good quality bread. Similar effects on grain weight and specific weight have also been observed in wheat [11, 20], barley [13, 21], and oats [22]. In the UK, the harvest year of 1992 was a severe lodging year with 16% of the wheat area lodged [23]. In this year the national average HFN fell from a 5-year average of 287 s to 254 s, thus significantly reducing the amount of bread making grain produced in this year.

Lodging Resistance in Cereals. Figure 2
Sprouting in a lodged wheat crop

Lodging Resistance in Cereals. Figure 3
Wheat plants leaning as a result of root lodging

Also in this year, the specific weight of wheat grains fell from 77 kg hl^{-1} to 73 kg hl^{-1} and the number of small grains (<2.0 mm) increased from 1.9% to 2.6% [24]. It is likely that at least a proportion of these effects were caused by the greater than usual lodging experienced in this country during this year.

Mechanisms of Lodging

Lodging can either occur through stem buckling (stem lodging) or displacement of the roots within the soil (root lodging) (Fig. 3). During stem lodging the roots are held firmly in a strong soil and the wind force buckles the stem. Stem lodging can occur due to buckling of the lower internodes. Buckling of the middle internodes is commonly known as "brackling" and is often observed in barley (Fig. 4) [25] and oats. Buckling of the peduncle just below the ear is known as "necking" and occurs most frequently in barley [26]. Root lodging becomes more likely when the anchorage strength is reduced by weak soil or poorly developed anchorage roots. Rainfall can reduce soil strength by several fold and has an important influence on the anchorage strength of cereals.

Very few observations have been reported of the lodging process as it occurs and conjecture exists as to whether stem lodging or root lodging predominates in cereals. Wheat and barley have been observed to root lodge [27, 28] and to stem lodge [25]. However, recently a quantitative understanding of root and shoot

Lodging Resistance in Cereals. Figure 4
Brackling in barley

lodging has been developed for wheat and barley showing that both types of lodging are possible depending on the circumstances of a particular crop [29, 30]. This has been confirmed in wheat by direct observations of both mechanisms occurring during wind-tunnel experiments on field-grown winter wheat [31].

The lodging models described by Baker et al. [29] and Berry et al. [30] calculate the wind-induced base bending moment of a shoot from plant characteristics

and meteorological data. The base bending moment is then compared to the failure moments (strength at the point of failure) of the stem base and of the anchorage system. Stem lodging is assumed to occur when the base bending moment of a single shoot exceeds the failure moment of the stem base. Root lodging is assumed when the base bending moment of all the shoots belonging to a single plant exceeds the failure moment of the anchorage system. The following sections describe current understanding about how the components of lodging (base bending moment, stem failure moment, and anchorage failure moment) may be calculated and what factors influence them.

Base Bending Moment

The wind-induced force acting on the upper sections of a shoot or plant results in a bending moment at the plant's base. This can be described as the shoot leverage. The coherent waving of cereal shoots, apparent even in light winds, provides evidence that cereal shoots are subjected to varying forces and illustrates the importance of including the shoot's motion in any calculation of the applied base bending moment. Baker [32] attempted to account for the dynamic nature of shoot movement by considering the forces that act on an idealized shoot and assuming that the shoot's movement could be modeled as damped harmonic oscillator. The theoretical modeling work described in [32] and [29], which was later validated in wind-tunnel experiments using field crops [31], showed that the wind-induced base bending moment of wheat could be calculated from a range of environmental and plant inputs. These include: the wind speed at crop height, the natural frequency of the shoot (rate at which it oscillates), the damping ratio of the shoot (which describes the rate at which oscillations die out), the height at center of gravity of the shoot, and the projected area and drag coefficient of the ear. These parameters can be used to estimate the bending moment at the base of the shoot for a shoot with a stiff stem such as wheat. Additional parameters are required to estimate the bending moment of more flexible stems such as for barley and include the flexural rigidity of the stem and its fresh weight. A method for calculating the bending moment of flexible stems is described in [30].

Anchorage Failure Moment

There is uncertainty about the exact mechanism of anchorage failure in cereals due to the obvious difficulty associated with observing the process in field conditions. Ennos [33] showed that anchorage failure of spring wheat involved bending of the crown roots and resistance to axial movement through the soil. Crook and Ennos [27] showed that the upper portions of the crown root system of winter wheat form a cone (Fig. 5) and anchorage failure occurred when the root-soil cone rotated at its windward edge, the soil inside the cone moved as a block and compressed the soil beneath. This idea supported earlier observations by Pinthus [34], who showed that a wider angle of root spread was related to greater resistance to root lodging. Easson et al. [35] suggested that winter wheat roots acted like ropes to withstand root lodging and that anchorage strength would therefore be a function of the tensile strength of the roots on the windward side of the plant.

The model developed by Crook and Ennos [27] has been tested and calibrated with field experiments on wheat [29] and on barley [30] (Fig. 6). These experiments showed that the anchorage strength was linearly related to the product of the diameter of the root cone cubed, the shear strength of the surrounding soil, and a constant specific to wheat or barley. The size of the

Lodging Resistance in Cereals. Figure 5
Upper portions of the root system of winter wheat

Lodging Resistance in Cereals. Figure 6
The product of soil shear strength (s) and root plate spread cubed (d^3) plotted against failure moment (B_R) for winter barley (o; y = 0.58x, R^2 = 0.95) and for winter wheat (5; y = 0.39x, R^2 = 0.69) (Adapted from [30])

root plate is identified by the parts of the crown roots that are surrounded by a rhizosheath. The rhizosheath is a dense mat of hairs that cover the upper sections of crown roots. These sections of roots have been shown to have an outer ring of lignified tissue in addition to the lignified central stele [27], which is why the rhizosheath can be used to estimate the length of root that provides anchorage.

The observation that anchorage strength was linearly related to the spread of the diameter of the root cone for both wheat and barley strongly suggests that both species have the same mechanism of anchorage failure first described by Crook and Ennos [27]. However, it was apparent that the constant factor was different between species with a value of 0.39–0.43 for wheat [29, 30] compared with 0.58 for barley demonstrating a greater anchorage strength for a given root plate spread for barley. This may have been caused by the greater number of stems per mm of root plate for barley compared with wheat. Up to 20 mm of the stem base is below ground, so it seems likely that a greater number of stems will increase the rotational resistance of the anchorage system.

A model of soil strength developed by Baker et al. [29] showed that variation in clay content, moisture content, and compaction that is normally found within farmer's fields could each be expected to alter the soil shear strength by several fold. This indicates that the state of the soil is likely to be of paramount importance for determining lodging given that it has been predicted in the anchorage model described above to be directly proportional to anchorage strength.

Stem Failure Moment Assuming that a typical stem can be considered to be analogous to a cylinder, Baker [32] showed that the stem failure moment (B_S) can be expressed as:

$$B_S = \frac{\sigma \pi a^3}{4}\left(1 - \left(\frac{a-t}{a}\right)^4\right)$$

where σ is the stem failure yield stress (material strength), a is the external radius of the stem, and t is the wall thickness. This formula assumes that the pith in the center of the stem does not contribute to the structural properties of the stem. Experiments by Neenan and Spencer-Smith [25] have shown that the stems of wheat and barley buckle at a certain critical ratio of radius of curvature to the outside diameter of the stem. Buckling was shown to occur suddenly with negligible amounts of plastic deformation. The Young's modulus of wheat and barley was shown to remain reasonably constant for a range of stem curvatures which indicates that negligible plastic deformation occurs and that the limit of proportionality between the applied stress and corresponding strain is seldom exceeded. It may therefore be concluded that stem lodging occurs abruptly and will result in complete structural failure of the stem.

Influence of Crop and Environmental Characteristics on Lodging Risk

Lodging is a complex process that involves several environmental and plant characteristics. Any assessment of the effect of individual characteristics on lodging risk must account for interrelationships between characteristics. To date the only study to have achieved this involves a sensitivity analysis of the lodging model of Baker et al. [29] and this is described in [9]. This study further developed the model of Baker et al. [29] to account for spatial non-uniformity between plants and temporal changes in plant structure during the growing season. A sensitivity analysis using this

model showed that the risk of stem lodging is influenced most by changes in stem diameter and the risk of root lodging is affected most by changes to the diameter of the root cone (also referred to as the spread of the root plate) (Fig. 7). In these analyses, the risk of lodging is measured in terms of the wind speed required to cause lodging, which is termed the "stem" or "root" "failure wind speed." The large effect on

Lodging Resistance in Cereals. Figure 7

Failure wind speeds after 7 mm rain for (**a**) internode 1 and (**b**) anchorage. The ranges (0–1) are judged to represent the combined genetic and environmental range of each parameter within a high yielding wheat crop (Adapted from [9]). Stem radius – radius at the mid-point of the lowest internode; stem wall width – wall width at the mid-point of the lowest internode; stem failure yield stress – material strength of the stem wall of the bottom internode; center of gravity – height at center of gravity of the main shoot; natural frequency – rate at which the shoot oscillates; ear area – projected area of the ear; drag coefficient – resistance offered by the ear to wind; damping ratio – rate at which the shoot's oscillations stop; shoot number – number of fertile shoots per plant; root spread – diameter of the root plate defined by the thickened regions of the crown roots; root depth – depth of the root plate defined by the thickened regions of the crown roots

Lodging Resistance in Cereals. Figure 8
Probabilities of experiencing wind gusts independent of rainfall (—) and wind gusts with $\geq$ 7 mm daily rain (---) between mid-June and mid-August within the main wheat-growing regions of the UK (Adapted from [9])

the chance of lodging caused by small changes in the failure wind speed is illustrated by the probabilities of experiencing different wind speeds above a UK wheat crop (Fig. 8).

Methods for Controlling Lodging Risk

Crop Management

Cultivations The use of minimal cultivations or direct drilling to prepare seed beds have been shown to reduce lodging compared with more traditional methods which usually involve plowing to about 20 cm depth [36]. It seems likely that observations for direct drilling or minimal cultivations to reduce lodging are mainly caused directly by increased soil strength resulting from greater bulk density [37, 38]. The common observations for high bulk density to impede root extension and increase root thickness [39, 40] appear to be restricted to sections of the cereal root system that play little part in anchorage, namely, the seminal roots or the distal sections of the crown roots.

Rolling to consolidate the soil is another management practice that has been shown to reduce lodging [34, 41–43]. This can be done immediately after the primary cultivations or can be done in spring to re-consolidate the top-soil after it has been loosened by cycles of freezing and thawing. Berry et al. [43] showed that rolling a sandy loam in the spring increased shear strength in the top 5 cm by 25% and this effect persisted until harvest. No effects were observed on the biomechanical properties of the wheat roots. This study also showed that rolling before growth stage (GS) 30 [44] reduced lodging, but rolling after GS31 had no effect on lodging. It was hypothesized that this treatment damaged the extending stems, which encouraged extra tillering, and these extra shoots countered the effects of the stronger soil. This theory was supported by rolling experiments to break cereal stems by Peltonen and Peltonen-Sainio [45].

Sowing Date and Seed Rate The lodging risk of wheat is almost always reduced by delaying sowing [19, 46–49]. Pinthus [50] cites two studies that show reduced lodging in barley when it is sown later, but [47] observed that early sowings could reduce or increase lodging in barley. Reducing the number of plants established also causes a large reduction in the lodging risk of wheat [12, 19, 48, 51–53], and of barley [54].

The sowing date and seed rate effects described above are caused by changes to the structure of the crop. Berry et al. [48] showed that sowing winter wheat 6 weeks earlier increased both root and stem lodging risk by increasing the base bending moment of the shoot by about 30% and by reducing the strength of the stem base and the strength of the anchorage system by about 50%. Stapper and Fischer [19] have shown that early sowing results in a greater number of extended internodes, and this probably caused the longer stems which gave rise to the greater base bending moment. Establishing 200 plants m^{-2} compared with 400 plants m^{-2} reduced lodging risk by increasing the strength of the anchorage system by more than 50% and the strength of the stem base by 15% [48]. The increase in anchorage strength more than compensated for the increase in shoot number on these plants. The greater anchorage strength has been attributed to several morphological changes including more roots per plant [12], stronger and thicker roots [55], and a wider and deeper root cone [48].

Sowing earlier or establishing more plants resulted in weaker stems because the stems were narrower and had thinner walls [48]. The mechanism by which weak stems develop is thought to be due to a greater number of shoots competing for limited photo-assimilate

during early stem extension, which reduces the dry matter per unit length of the lower internodes [56]. Sparsely populated plants have many tillers [57] each of which develops up to four crown roots from each of their subterranean nodes. Therefore, it should be of no surprise that establishing fewer plants results in plants with more crown roots. Thicker and stronger roots may be caused by the absence of a strong shade avoidance response by the plant, which stimulates a greater proportion of assimilate to be partitioned to the roots [58]. Similar effects on anchorage strength were observed after later sowing as a result of fewer plants established.

Drilling Depth and Seed Treatment Deeper sowing has also been found to reduce lodging in barley [50], but in general published evidence for sowing depth effects is scarce. This is probably caused by the plants ability to adjust its crown depth to about 40 mm for sowing depths of between 40 and 70 mm [59]. This means that sowing depths over this range are unlikely to affect the depth of the structural roots. However, drilling more shallowly than 40 mm may be expected to raise the crown and its structural roots, thus weakening anchorage.

Evidence that altering crown depth can affect lodging can be found from the effect of seed treatments: fluquinconazole [60] and triadimenol [61]. Studies on fluquinconazole showed that it shortened the sub-crown internode linking the seed to the crown (the part of the plant where the crown roots and tillers emerge). This deepened the crown and the depth of the root plate, which in turn increased anchorage strength and the resistance to root lodging. Observed natural root lodging also showed that the plots treated with the triazole seed treatment were less susceptible to root lodging [60].

Disease Scott and Hollins [62] showed that wheat crops with a greater incidence of sharp eyespot (*Rhizoctonia*), brought about through inoculation, had more lodging. It has been shown that severe levels of either disease can reduce the failure moment of the lower internodes by between 30% and 40%, thus increasing the likelihood of stem lodging [10]. Interestingly, slight or medium levels of disease did not appear to weaken the stems. There is no evidence that take-all root disease increases the risk of lodging.

Nutrition An increased supply of available nitrogen from either mineralization of organic matter or from inorganic fertilizer has frequently been shown to increase lodging in wheat [48, 63, 64], barley [26, 65], and oats [66]. In wheat, the greatest increase in lodging is usually observed in response to early applications of nitrogen fertilizer before the onset of stem elongation [22, 23, 67], with applications after anthesis having no effect [52]. Contrary to this, Chalmers et al. [66] found that lodging in winter oats was reduced by applications of nitrogen before the onset of stem extension compared with later applications at GS30/31.

Both Crook and Ennos [68] and Berry et al. [48] showed that increasing the nitrogen supply to winter wheat, through either greater amounts of soil residual nitrogen at sowing or through larger applications of fertilizer in the spring, reduced the strength of the stem base and, to a lesser extent, reduced the strength of the anchorage system. Increases in crop height were generally small. Reductions in stem strength could be as much as 50% when high levels of residual nitrogen were combined with applications of fertilizer early in the spring [48]. Greater nitrogen supply almost always decreases the dry weight per unit length of the basal internodes of wheat [27, 48], barley [26], oats, and rye [22]. In relation to this, stem diameter and stem wall width are also frequently reduced. Berry et al. [48] showed that high levels of residual nitrogen reduced the strength of the stem wall material. These findings were supported by Crook and Ennos [27], who showed that a component of material strength, Young's modulus (which approximates to the stiffness of the stem), was also reduced by more fertilizer in spring. The cause of these effects may have resulted from a reduced amount of lignified tissue within the sclerenchyma zone and the thickness of the sclerenchyma cell walls [22]. Reductions in anchorage strength in response to more nitrogen can be linked with fewer roots, which are thinner with smaller bending and tensile strengths [55, 68]. Mulder [22] showed that the crown roots of oat plants supplied with large amounts of nitrogen were practically free from lignified cells beneath the epidermis, in contrast with plants supplied with moderate amounts of nitrogen.

In the consideration of nutrition, there should be a differentiation between the effects that result from repairing a deficiency and effects resulting from

super-optimal supply. For example, it appears that an increase in nitrogen will increase lodging risk, but the mechanism by which this occurs will depend on the level of nitrogen supply. If a nitrogen deficiency is being repaired then lodging risk increases because the leverage of the shoot and ear increases. It seems likely that the stem strength, and possibly the anchorage strength, will be increased by correcting the deficiency but these effects are outweighed by the greater leverage. Additional nitrogen increases the shoot leverage by progressively smaller amounts, but lodging risk continues to rise because the strength of the stem base and root system begins to decrease as a result of the indirect effects of shading. It is possible that phosphorus behaves in a similar way to nitrogen [67]. However, potassium might be different as the evidence [22, 50, 69] indicates that it can reduce lodging when repairing a deficiency and additional amounts have no effect. This may be due to the important role that this element plays in regulating the turgor of plant tissues.

Plant Growth Regulators Plant growth regulators (PGRs) are synthetic compounds that can be used to reduce lodging in cereal species. They are most commonly used for this purpose in north and western European countries and in North America. In the UK, 89% of the winter wheat is treated with PGRs [70]. PGRs can be classified into two main groups: inhibitors of gibberellic acid biosynthesis and ethylene-releasing compounds. The most commonly used inhibitors of gibberellic acid biosynthesis in cereal crops are chlormequat chloride, mepiquat chloride, trinexapac-ethyl and prohexadione-calcium [71]. Ethephon is the most commonly used ethylene-releasing compound used on cereals [72].

Plant growth regulators have been shown to be a cost-effective method of reducing the incidence of lodging. PGRs applied before the emergence of the ear reduced lodging in almost all of the vast number of published experiments that have studied their effect and in which lodging occurred, with reductions in the percentage area lodged of anything up to 70% [10]. The primary mechanism by which PGRs have been shown to reduce lodging risk is by reducing crop height, with height reductions of up to 40% [10]. The variation on plant height reduction is probably caused by interactions between the type of active ingredient, the cereal species together with the stage of plant development, and the environmental conditions when the chemical is applied. No evidence has been found for PGRs to increase the strength of the stem or of the anchorage system [48, 68], although it must be recognized that only two studies have investigated the effects of PGRs by directly measuring stem and anchorage strength. Chlormequat has been shown to be effective at reducing lodging in winter and spring wheat, oats, and rye, but less effective on barley [73, 74]. Barley undergoes large height reductions in response to a mixture of ethephon and mepiquat chloride [13, 75].

Summary of Crop Management Effects Many crop management practices result in large changes in lodging risk by either affecting the wind-induced leverage of the shoot, the strength of the stem base, the strength of the anchorage system, or a combination of all three mechanisms. Furthermore, the strengths of the stem base and anchorage system are often changed by different amounts for any change in crop management. This means that certain types of crop management would be expected to reduce one type of lodging (stem or root) more than the other. The effects of several crop management practices on the risk of stem and root lodging have been summarized by Berry et al. [76] in terms of changes to the failure wind speed (Table 1). This shows that stem lodging is best reduced by sowing on soils with less residual nitrogen and by reducing and delaying the amount of fertilizer applied in the spring. Root lodging is best reduced by establishing fewer plants, using a seed treatment with growth regulatory properties and by rolling in the spring to consolidate the soil. Delayed sowing and growth regulators were estimated to reduce stem and root lodging by equal amounts.

Plant Breeding

The *Rht* (Reduced height) alleles began to be introduced into wheat varieties during the 1960s and 1970s and are now part of the germplasm of most high yielding semi-dwarf varieties. In UK and German wheats, *Rht*1 and *Rht*2 alleles can reduce height by 14–17% independently of each other and by 42% when in combination [2]. *Rht*3 can reduce height by 59%, but has not yet been used in commercial varieties.

Lodging Resistance in Cereals. Table 1 Effect of crop management on the wind speed required to cause stem or root lodging (Adapted from [60, 76]

Factor	Increase in stem failure wind speed ms^{-1}	Increase in root failure wind speed ms^{-1}
Less soil residual N (116–71 kg N ha^{-1})	2.3 (3.9 [a])	1.3
Seed treatment with PGR activity (e.g., Fluquinconazole [60])	0	0.7
Delayed sowing (per week, between 20 September and 1 November)	0.5	0.5
Less plants established (per 100 plants m^{-2}, between 400 and 200 plants m^{-2})	0.8	1.8
PGRs (split chlormequat @ GS30/31)	1.4	1.4
Delayed and less fertilizer N (Target GAI of 5)	1.4	0.8
Spring rolling (pre-GS30)	0	0.8

[a]At 400 plants m^{-2}

In the UK, the *Rht*1 and *Rht*2 alleles have helped to reduce the height of wheat cultivars from over 1 m to about 0.7–0.9 m between the early 1970s and the mid-1990s. This reduction in height and consequent reduction in leverage has enabled the amount of nitrogen fertilizer applied to wheat to be increased from less than 100 kg ha^{-1} in the early 1970s to nearly 200 kg ha^{-1} in the 1990s [77] without a dramatic increase in the incidence of lodging. Pleiotropic effects have further added to the yield improvements associated with these *Rht* genes in wheat. Reduced stem growth rates allow more resources to be allocated to the developing ear which results in a greater number of fertile florets and grains per year.

In oats, the variety S172, released in 1939, has been reported to be Europe's first dwarf cereal variety [78]. However, dwarfness in this and several derived varieties was associated with small grains and a yield penalty. Recently varieties have been released that contain the *DW-6* dwarfing gene which was discovered in a mutation program in Canada [79] and has been shown to shorten the peduncle [80]. This gene has been shown to reduce height by 20–75 cm, have thicker stems, and to reduce lodging by large amounts [81]. Major dwarfing genes are common in spring barley. The *ari-eGP* dwarfing gene was found in cvs Golden Promise and Midas, which comprised over 70% of the Scottish barley crop from the mid-1970s to early 1980s. The *ari-eGP* gene was then superseded by the *sdw1* dwarfing gene, such that by 1989 the percentages of certified seed carrying the sdw1 and ari-eGP genes were 74 and 8, respectively [82].

There is great potential to continue increasing lodging resistance through further height reductions via the introduction of more extreme dwarfing genes such as *Rht*3 in wheat. However, several studies have shown that yield is reduced when crops are shortened too much [2–7]. The reduction in yield appears to be exacerbated by high temperatures or drought stress. Several of these studies indicate that the minimum crop height for optimum yield lies between 0.7 m and 1.0 m, a height which many modern varieties have already achieved. There is evidence that the same problem could occur in oats because the *DW-6* dwarfing gene has been associated with small grains, low kernel content and poor extrusion of the panicles from the flag leaves in some genetic backgrounds [81]. It therefore seems unlikely that much further improvement in lodging resistance can be made by continuing to shorten wheat crops and there may be only limited further shortening possible in other cereal species. As a result breeders must target other plant traits, namely, stem strength and anchorage strength, to improve lodging resistance and counter greater yields.

The lodging model of Baker et al. [29] has been used with preliminary datasets describing the dry matter costs of improving traits associated with stem strength and anchorage strength to estimate the dimensions of

Lodging Resistance in Cereals. Figure 9
Description of a lodging-proof ideotype for wheat grown in a UK environment as defined in [83]

a wheat plant to make it lodging-proof for the least investment of biomass in the supporting stem and root system [83]. The characteristics required to give a crop yielding 8 t ha^{-1} with 500 shoots m^{-2} and 200 plants m^{-2} a lodging return period of 25 years in a UK environment include a height of 0.7 m, a root plate spread of 57 mm, and for the bottom internode a wall width of 0.65 mm, a stem diameter of 4.94 mm, and a material strength of 30 Mpa (Fig. 9). Observations of a range of varieties grown in the UK showed that the root plate of the best variety was 7 mm less than the ideotype target, the widest stem was 0.5 mm below the ideotype target, other stem character targets were achieved but not all in one variety, and the height target was achievable with the use of plant growth regulators.

It is possible that the lodging-proof ideotype traits could be achieved because large differences among wheat varieties have been observed for the traits that determine stem strength and anchorage strength [42, 76, 84]. The latter study showed that anchorage strength could vary from 206 Nmm to 587 Nmm and stem strength could vary from 122 Nmm to 175 Nmm between varieties. These differences were caused by a combination of wider, deeper root plates and stiffer roots for anchorage strength, and wider, thicker walled stems with a greater material strength for overall stem strength. Subsequent studies using more varieties and breeding lines showed even greater genetic variation in the traits which determine stem strength and anchorage strength [83, 85]. In barley, differences in culm wall thickness have frequently been positively correlated with varietal differences in lodging resistance [86–88]. If oats and barley have a similar level of genetic variation in stem and anchorage strength as has been observed in wheat then there appears to be significant scope for breeders to improve the strength of the stems and anchorage systems of cereals. However, these traits are time-consuming to measure; therefore, new technologies will be required to help plant breeders to rapidly select them.

Future Directions

The majority of lodging research has concentrated on wheat. This has enabled models of the lodging mechanism to be developed, which have been used to identify the critical plant characters, to quantify the effects of factors on lodging and to elucidate the mechanisms by which these effects are caused. A rudimentary model of lodging has been developed for barley, but further work is required to fully validate this model, particularly the way in which flexural rigidity of the stem is considered. Understanding about lodging in other cereals, such as rice, maize, and oats, lags far behind wheat. In order to replicate the advances made in wheat the next step must be to model the lodging mechanisms in these cereals. This may require fundamentally different types of lodging model due to the different plant structures of these species.

Historically reducing crop height has been the main avenue by which the lodging risk of wheat has been reduced. However, several studies on wheat indicate that the minimum height compatible with high yields is around 0.7 m. This height has been achieved by many wheat varieties. Crop height also has a major impact on the structural dry matter requirements for lodging resistance with each additional centimeter in height increasing the stem dry matter required by 0.23 t/ha [83]. Further work must investigate why there appears

to be a minimum height for high yield, whether this barrier can be overcome and whether the minimum height for high yield varies between environments.

Preliminary studies with wheat have indicated that increasing stem strength has a significant dry matter cost which could compete with the formation of grain yield [83]. Further work must quantify the dry matter cost of increasing stem strength, understand the optimum combination of stem diameter, wall width, and material that is required to minimize the dry matter cost of increasing stem strength, and quantify the extent to which this competes with yield formation.

It has been predicted that breeders must increase the stem strength and anchorage strength of wheat in order to achieve a lodging-proof ideotype for wheat. These traits are time-consuming to measure; therefore methods must be developed for rapidly assessing these traits. Berry et al. [89] and Keller et al. [90] have identified more than one quantitative trait loci associated with these traits and indicated that they are controlled by several genes. Further work will be required to better understand the genetic control of the traits associated with lodging and to investigate whether reliable genetic markers can be identified which work across a range of genotypes and environments. Phenotypic screens must also be investigated to assess whether they can offer an alternative method to genetic markers for selecting germplasm.

Recent work has shown that although a wide genetic variation for the key lodging traits is present within UK wheat breeding material [85], few of the target traits required for complete lodging proof have been identified. This indicates that a wider range of germplasm must be assessed to find the target traits.

Currently there is not a reliable method predicting the likelihood of lodging from earlier stages of crop development, when growers can alter lodging risk through their crop management (PGRs, fertilizer, rolling). Therefore, further research must study the development of the lodging-associated plant characters with the objective of predicting lodging from early assessments of the crop. Any prediction scheme must predict lodging risk before, or soon after, the onset of stem elongation to enable growers to alter their crop management accordingly.

PGRs reduce lodging risk by shortening crops, but there is little published evidence that they can strengthen the stems and anchorage system. Further research should investigate the effect of existing PGRs on stem and anchorage strength as well as focusing on discovering new chemicals that strengthen these traits.

Glossary

Biodiversity Variation of life at all levels of biological organization.

Disturbance A relatively discrete event in time and space that alters populations, communities, and ecosystems, including their attendant processes.

Ecology The study of the relationship of organisms or groups of organisms to their environment.

Ecosystem dynamics The observed changes in the characteristics of an ecosystem over time.

Ecosystem The organisms living in a particular area in combination with the physical elements of the environment in which they live.

Episodic Limited in duration or temporary.

Invisible present Relating to an observation whose importance cannot be evaluated for lack of context.

Scale Refers to differences in the spatial or temporal extent of a set of observations or measurements.

Synthesis The creation of new knowledge by combining observations from diverse sources.

Transformative research Scientific investigations whose results lead to radical changes in understanding of fundamental concepts.

Definition of the Subject

The Long-Term Ecological Research (LTER) Network is the largest and longest-lived ecological network in the United States. Designed to provide long-term data from a broad range of key ecosystems, the LTER Network represents a unique national resource to address pressing environmental issues such as climate change, loss of biodiversity, and changes in patterns of land use. LTER is recognized internationally as one of the best organized and most successful large groups conducting research in ecology. With over 1,500 scientists, educators, and students, the network spans 26 sites located in 16 states in the contiguous United States, Alaska in the Arctic, Antarctica, and islands in the Caribbean and the Pacific Ocean (Fig. 1).

The network's formal vision is a society in which long-term ecological knowledge contributes to the advancement of the health, productivity, and welfare of the global environment, thereby advancing human well-being [2]. Within this vision, LTER's mission is to provide the scientific community, policy makers, and society with the knowledge and predictive understanding necessary to conserve, protect, and manage the nation's ecosystems, their biodiversity, and the services they provide. The LTER Network achieves this mission by using long-term observations and experiments to generate and test ecological theory at local to regional scales.

The National Science Foundation (NSF) created the LTER program in 1980. For three decades, the network has generated rigorous, site-based scientific research that has led to important regional and continental syntheses. LTER provides the scientific expertise, research platforms, and long-term datasets necessary to document and analyze environmental change.

Introduction

Because some of the most interesting and important ecological phenomena take place over long periods,

Long-Term Ecological Research Network. Figure 1

Locations of current LTER sites within global ecoregions. Site names, acronyms, and home institutions are as follows: Andrews Experimental Forest LTER (AND) – Oregon State University; Arctic LTER (ARC) – The Ecosystems Center, Marine Biological Laboratory; Baltimore Ecosystem Study (BES) – Cary Institute of Ecosystem Studies; Bonanza Creek LTER (BNZ) – University of Alaska – Fairbanks; California Current Ecosystem (CCE) – Scripps Institution of Oceanography; Cedar Creek Natural History Area LTER (CDR) – University of Minnesota; Central Arizona – Phoenix (CAP) – Arizona State University; Coweeta LTER (CWT) – University of Georgia; Florida Coastal Everglades (FCE) – Florida International University; Georgia Coastal Ecosystems (GCE) – University of Georgia; Harvard Forest (HFR) – Harvard University; Hubbard Brook Experimental Forest LTER (HBR) – Cornell University; Jornada Basin (JRN) – New Mexico State University; Kellogg Biological Station (KBS) – Michigan State University; Konza Prairie LTER (KNZ) – Kansas State University; Luquillo Experimental Forest LTER (LUQ) – University of Puerto Rico; McMurdo Dry Valleys (MCM) – Ohio State University; Moorea Coral Reef (MCR) – University of California-Santa Barbara; Niwot Ridge LTER (NWT) – University of Colorado; North Temperate Lakes (NTL) – University of Wisconsin-Madison; Palmer Station (PAL) – The Ecosystems Center, Marine Biological Laboratory; Plum Island Ecosystems (PIE) – The Ecosystems Center, Marine Biological Laboratory; Santa Barbara Coastal (SBC) – University of California-Santa Barbara; Sevilleta LTER (SEV) – University of New Mexico; Shortgrass Steppe (SGS) – Colorado State University; Virginia Coast Reserve (VCR) – University of Virginia (Courtesy of Jamie Hollingsworth; data from The Nature Conservancy [1])

long-term observations or experiments are necessary to truly understand their impacts. Processes such as climate change, recovery after disturbances such as forest fires, and changes in land cover are ecological processes that must be studied over the time scale of their occurrence (see, e.g., [3, 4]). Consequently, studies over sufficiently long time periods and large geographical scales are necessary to permit generalizations and theory about long-term events – such as deforestation, acid deposition, grazing, fire, and changes in trace gas fluxes [5].

In the concluding summary to a special report entitled "Long Term Ecological Research: An International Perspective," Risser [6] noted that long-term ecological studies are especially useful under four conditions: (1) the phenomena being studied are long term in their dynamics; (2) are episodic in nature, rare, complex, or subtle, such that long-term experiments are needed to isolate their dynamics and the control processes; (3) are poorly understood and cannot be predicted from short time scales; or (4) when long-term records are needed to make policy decisions.

Although important, such long-term studies are generally rare, with only a few examples all across the globe (Fig. 2). According to Risser [6] long-term ecological studies are rare because: (1) long-term studies may not be considered innovative science, making their continuous funding difficult; (2) sites where the measurements are taken may change, making the long-term results meaningless or difficult to interpret; (3) experimental designs may be too ambiguous for consistent long-term measurements or may not include adequate auxiliary studies to unravel controlling processes; (4) resources or incentives may be inadequate for dedicated scientists or research leaders to continue the studies; (5) new instrumentation may render the original methodology obsolete, coupled with insufficient attention to calibrating the old and new technologies; (6) new scientific advances may make the original question or hypothesis uninteresting or may provide a definitive answer, making the studies unnecessary.

It was this dearth of reliable information on key long-term ecological processes that prompted NSF to create the LTER Network in 1980 (see section "Major

Long-Term Ecological Research Network. Figure 2
Frequency distribution of a random sample of observational and experimental studies published in the journal Ecology between 1977 and 1987 (From Gosz et al. [7]. Data from Tilman [8])

Long-Term Ecological Research Network. Figure 3

Temporal and spatial domains of the LTER program focus on biological phenomena and physical events that operate on year to century time scales and plot to regional spatial scales (Redrawn from Magnuson et al. [13], with permission)

Milestones in LTER" in this document for a brief history of LTER's formation). Acting on the recommendations of three working groups comprising members of the ecological community [9–11], the Division of Environmental Biology at NSF constructed a call for proposals designed to "(1) initiate the collection of comparative data at a network of sites representing major biotic regions of North America and (2) evaluate the scientific, technical, and managerial problems associated with such long-term comparative research" [12]. Although the early emphasis of the LTER program was on expanding the time scale at which ecological research was conducted, a concomitant expansion of the spatial scale of research was also expected (Fig. 3). This broadening perspective led to the twin concepts of the "invisible present" and the "invisible place."

Time and the Invisible Present

Magnuson [4] coined the term "invisible present" to describe ecological processes that result in significant change over decades but are hidden to the investigator conducting short-term studies. Ecologists working in this "invisible present" are not able to place current conditions in perspective without additional data from a longer span of time. Magnuson noted that short-term observations often could not identify cause and effect relationships because of inherent time lags of a year or longer between cause and effect. For example, changes in biomass accumulation in a forest as a result of disturbance may take years or decades to perceive. In short-term observational studies, it is rare to actually observe infrequent but important events. However, it is common to observe responses of an ecological system to an event that occurred long before observations began. Short-term manipulative studies often observe a system in transition rather than the complete trajectory to a new system state.

A good example of the importance of long-term data on the interpretation of ecological processes is given by observations of the ice cover records of Lake Mendota, WI (Fig. 4, [14]). The duration of ice cover in

Long-Term Ecological Research Network. Figure 4 Observations of ice cover records of Lake Mendota demonstrate the importance of broad temporal scale in rendering the present visible (From Magnuson et al. [14])

a single winter (1997–1998 in the example) might seem unremarkable without any other context. However, examination of successively longer segments of the 142-plus years of ice duration data provides the context to see the importance of that single year. A 10-year segment of data reveals that duration of ice cover in 1997–1998 was significantly less than the other 9 years of record [15], and that duration of ice cover varies considerably from year to year. A relationship between ice cover and an important feature of global climate, the southern ocean oscillation index [16, 17], is evident in the 50-year data segment, with 1997–1998 and other El Niño years having shorter durations of ice cover. The general warming trend in the data only becomes apparent within the complete record. What's more, the end of the little ice age about 1890 [18, 19] is reflected in the decrease in the duration of ice cover on Lake Mendota. The single observation from 1997 to 1998, viewed in the context of the complete data set, is revealed to be the year of shortest ice duration in the entire 142-year record. Thus, the long-term nature of this set of observations provides a clear context to interpret patterns at multiple temporal scales.

Space and the Invisible Place

In the same way that a point in time requires long-term temporal context for complete understanding, so a point in space requires a broad-scale spatial context [20]. Interpretation of observations at a single site (the invisible place) requires a spatial context that often spans multiple scales. In the LTER Network, observational or experimental studies are often designed and implemented at the plot scale, where the plot may encompass less than 1 m^2 or an entire watershed. Most LTER site research focuses on plot to landscape scales (Fig. 3), but the use of remote sensing and modeling approaches, the steady development of networked interactions among sites [21], and the growth of the long-term approach internationally provides the means to expand the research focus to regional, continental, and global scales [20].

The study of glacial lakes at the North Temperate Lake's LTER site in northern Wisconsin illustrates a typical approach to linking ecological elements in a broader spatial context. Although lakes in this

landscape have many shared characteristics, the relative position of lakes connected along elevation gradients explains much significant dissimilarity, even in areas of slight relief. Lakes that are higher in the landscape are smaller, clearer, more dilute chemically, less diverse, and less affected by human use [22]. This pattern pertains to other lake districts throughout the northern hemisphere.

LTER scientists use two general approaches to extend results from small-scale and short-term studies to regional and broader scales [23]. An empirical approach correlates values of ecological processes with aspects of the physical environment that are measurable at broad spatial scales using specialized tools including remotely sensed imagery. For example, Kratz et al. [24] compared patterns of spatial and temporal variability across 12 LTER sites using normalized difference vegetation indices (NDVI) from Landsat scenes. They found that variability within sites for a given year was considerably greater than variability among sites, indicating that studies of spatial heterogeneity must be coupled with long-term data to achieve an understanding of long-term dynamics at landscape and regional scales.

A second approach uses mechanistic models to simulate interactions among ecological processes measured at sites and predict patterns at broader scales [23]. Data from the LTER Network facilitate construction of mechanistic models in two important ways. Coordination among sites within the network produces consistent, multidisciplinary data sets over a broad geographic range. The existence of data on slow ecosystem processes, which govern long-term ecosystem dynamics, allows estimation of rate constants needed to model these dynamics. One example of the interaction between long-term data and mechanistic models is the photosynthesis and evapotranspiration model (PnET) developed by Aber and colleagues to predict ecosystem processes at regional scales [23]. The PnET models form a nested hierarchy of three models estimating (1) gross and net carbon (C) gain on a daily time step, (2) net C and water fluxes at variable time steps, and (3) biomass, litter fall, decomposition, and nitrogen (N) cycling. Together the three models allow prediction of the integrated function of ecosystems. Predictions from the models have been compared with long-term C, water, and nutrient balance data from the Harvard Forest and Hubbard Brook LTER programs. Discrepancies between predictions and empirical data instruct model improvement and guide site research. The PnET models allow regional scale prediction of integrated ecosystem characteristics over a wide range of future environmental conditions and previous land use histories [23].

Networks of integrated research sites provide the opportunity to examine continental scale ecological patterns and the drivers of those patterns. One multisite, long-term experiment (the Long-Term Intersite Decomposition Experiment or LIDET) manipulated substrate quality across a broad range of vegetation and climate conditions to understand the factors controlling decomposition. Results from standardized measurements at 26 sites (17 LTER sites) indicated that decomposition of low-quality litter across a broad range of environmental conditions was slower than had been previously thought [25] and that significant variability resulted from ecosystem-specific factors such as the composition of the decomposer community. Studies such as these led LTER scientists to develop a conceptual framework for continental-scale research based on connectivity of flows of materials, organisms, and information across scales [26]. This framework emphasizes the importance of coordinated approaches across different research networks at continental and global scales.

Coordination of long-term ecological research at a global scale was initiated in 1993 through the formation of the International Long Term Ecological Research Network [27], which now has research networks in 40 countries. As a founding member of this global network, the US LTER Network continues to play a central role in developing research to address global ecological issues. In addition, many LTER sites perform observations and conduct experiments as part of global networks focused on specific research questions. For example, LTER sites are engaged in global comparisons of forest structure through the Center for Tropical Forest Science at the Smithsonian Tropical Research Institute. This network includes 40 plots in 21 countries encompassing 4.5 million individual trees of 8,500 species.

Major Milestones in LTER

Scientific investigation at and among LTER sites is dynamic and evolves continuously in response to increasing knowledge and new opportunities. The commitment of LTER sites to long-term observations and experiments does not imply rigidity in focus and approach. The ability of LTER researchers to respond nimbly to new opportunities results from a flexible network structure with a minimum of requirements and uniform site activities. This flexibility would not be possible in a more monolithic network design. Thus, during the first decade of LTER (the 1980s), key concepts of long-term ecological research were explored and clarified. In the 1990s, there was an increased emphasis on large spatial scales and multiple interactions of ecological processes, species, and element cycles. In addition, interactions with physical and social scientists also increased. The third decade of the LTER program focused on synthesis. Using data and knowledge gained over the preceding 20 years, the LTER Network sought to reach new levels of understanding of long-term and large-scale ecological patterns and processes. This summary of the intellectual evolution of LTER provides context for a description of the major milestones in the development of LTER research.

Formation of the Network

The seeds of LTER were planted by the National Science Foundation (NSF) when it sponsored three workshops (in 1977, 1978, and 1979) to initiate and maintain close consultation with the ecological sciences community. At these workshops, the philosophy of collaborative research was developed and a centralized working hypothesis approach to collaboration proposed. Five core areas of research (Box 1) were defined to orient long-term ecological research projects toward question/hypothesis formulation and resolution over long time and broad spatial scales.

Box 1. Core Research Areas

The core areas are five research themes that are common to research at all sites and thus central to the coordination of network science. Core areas were originally selected by NSF to ensure appropriate breadth in LTER research programs and to guard against divergence among sites over time. Combined, the five core areas describe most of the major structural components of ecosystems. Although discussions about adding new core areas (e.g., biodiversity, social patterns and processes) have taken place within the LTER Network, none of these have been officially adopted.

The core areas are:

1. *Pattern and control of primary production* – Plant growth in most ecosystems forms the base or "primary" component of the food web. Spatial and temporal patterns of production and the controls of these patterns are major factors in structuring ecosystems.
2. *Spatial and temporal distribution of populations selected to represent trophic structure* – Populations of organisms are dynamic over space and time, and long-term trends in populations can be important indicators of environmental change.
3. *Movement of organic matter* – The sequestration of carbon by primary producers and its eventual fate in ecosystems have important implications for trophic dynamics, nutrient cycling, and global climate.
4. *Movement of inorganic matter* – Nitrogen, phosphorus, and other mineral nutrients are cycled through the ecosystem by way of decay and disturbances such as fire and flood. Availability of these nutrients exerts important controls over ecosystem structure and function.
5. *Disturbance patterns* – Disturbances often shape ecosystems by periodically reorganizing physical or community structure, resulting in significant changes in ecosystem services available to humans.

Major Milestones in the First LTER Decade

1980 – NSF selected an initial set of six sites (North Temperate Lakes, H.J. Andrews Experimental Forest, Coweeta Hydrological Laboratory, Konza Prairie, North Inlet Marsh, and Niwot Ridge) funded at $250,000 per year. Lead scientists from each site met in Washington, DC, and constituted a steering committee to begin the tasks of LTER communication, coordination, and accommodation of mutual goals.

1981 – Dick Marzolf (Konza Prairie) was elected the first Chair of the Steering Committee and NSF awarded

Box 2. The LTER Network Office

The LTER Network Office (LNO) was established in 1983 through a coordination grant awarded by NSF to Oregon State University to support and coordinate network and site activities of the LTER Network. In 1989, NSF awarded another coordination grant to enlarge and establish LNO at the University of Washington-Seattle. The office officially moved to the University of New Mexico in 1997, and added the position of Executive Director. Robert B. Waide, formerly co-principal investigator of the Luquillo LTER program, was the first Executive Director of the LNO. With a core staff of 18 people and an annual budget of $1.5 million, the LNO's current service mandate includes:

- Providing an efficient computational and communication infrastructure for LTER research and education
- Developing and deploying state-of-the-art techniques in information management
- Maintaining a strong public outreach program
- Coordinating interactions with other scientific networks, agencies, and entities
- Providing administrative support
- Contributing to an efficient and effective environment in which site, cross-site, and synthetic research and education can be conducted

Box 3. All Scientists Meetings

Triennial All Scientist Meetings are used by the LTER Network to promote team building for cross-site research and synthesis. These 3–4 day meetings focus the LTER scientific community on new challenges, result in the formation of new research collaborations, help to integrate new sites and scientists into the LTER community, and provide the only opportunity for community-wide discussions of the future of the LTER program. In contrast to the usual scientific conference, an All Scientists Meeting focuses less on the presentation of individual research results and more on brainstorming, discussion, and synthesis of results from researchers addressing similar questions in different ecosystems. Moreover, All Scientists Meetings present excellent opportunities to share expertise, to transfer technology among sites, and to generate new scientific concepts, approaches, and experiments.

The most recent meeting in 2009 was attended by nearly 800 participants including many graduate students and broad representation for the International LTER community. The program included six plenary talks, 75 working group meetings, over 400 posters, four evening mixers, and pre-meetings for information managers, graduate students, education representatives, international attendees, and the LTER Executive Board.

a network coordination grant to Kansas State University (with Marzolf as PI). Subsequently, a second competition added five new sites to the network (Central Plains Experimental Range (now called Shortgrass Steppe), Okefenokee, Illinois Rivers, Cedar Creek Natural History Area, and Jornada Basin).

1982 – LTER held the first Data Management workshop and the first LTER Meteorological Committee (now Climate Committee) meeting, while the Steering Committee created a policy for workshops supported under the coordination grant.

1983 – NSF conducted the first national review of the LTER Program and the LTER Network Office (Box 2) was established through a coordination grant awarded by NSF to Oregon State University (with Jerry Franklin as PI).

1985 – LTER held its first All Scientists Meeting (Box 3) at Lake Itasca, MN.

1986 – NSF announced the third call for proposals for long-term ecological research sites; the LTER Intersite Climate Committee (formerly Meteorological Committee) developed standards for meteorological measurements at LTER sites [28, 29].

1987 – Five new sites (Arctic Tundra, Bonanza Creek Experimental Forest, Hubbard Brook Experimental Forest, Kellogg Biological Station, and Virginia Coast Reserve) joined the network; the LTER Intersite Climate Committee summarized climate information at the first 11 LTER sites [30]; and NSF announced the fourth call for long-term ecological research proposals.

1988 – Three new sites (Luquillo Experimental Forest, Sevilleta National Wildlife Refuge, and Harvard Forest)

Box 4. Evaluation of LTER Sites

NSF funds each LTER site independently for 6-year periods, with renewal of awards based on proposals describing accomplishments and plans for future activities. Renewal proposals are reviewed by special panels of experts convened by NSF. The review panel may recommend continued funding, preparation of an addendum addressing specific points, or probation. An LTER site that is placed on probation receives only 2 years of funding and must write a new proposal addressing shortcomings for the next renewal cycle 2 years later. If the new proposal addresses criticisms successfully, 4 more years of funding are awarded. If not, the site is provided with terminal funding to close operations. The purpose of the probation process is to ensure that NSF's long-term investment is protected from transient problems, such the death or retirement of leading investigators, while still maintaining high standards of rigor in peer review. Four sites have been terminated during the 30-year history of the LTER program.

NSF also conducts mid-term program reviews as an essential part of NSF's ongoing evaluation cycle of the LTER program. Midway through the funding period, external peer review teams visit each site to evaluate the quality of science, education, and outreach as well as how well the site is managed and how integrated the sites are with the entire LTER Network [31]. The site reviews also serve as opportunities for site scientists and staff to get constructive criticism from the review team and to identify potential problems that require correction [32].

were added to the program, while two (Illinois Rivers and Okefenokee) were withdrawn (Box 4); the NSF Advisory Committee on Scientific and Technological Planning for LTER identified scientific issues addressed by the sites and recommended network-wide capabilities to address them; and the minimum standard installation (MSI) for LTER site data management was developed.

1989 – NSF conducted a second national LTER Program review and awarded a coordination grant to enlarge and establish the LTER Network Office at the University of Washington-Seattle (with Jerry Franklin as PI); an LTER working group developed the "Global Change Research Action Plan"; acquisition of satellite imagery and aerial photography for all sites began; an LTER-Chinese Ecological Research Network (CERN) exchange was developed; and the first LTER Network Strategic Plan resulted from the 1989 LTER Coordinating Committee Meeting at Harvard Forest ("A long-range Strategic Plan for the Long Term Ecological Research Network").

Major Milestones in the Second LTER Decade

1990 – The LTER Coordinating Committee developed site data management policy guidelines; LTER held its second All Scientists Meeting at Estes Park, CO.

1991 – Following an NSF Antarctic research proposal competition, a new site, Palmer Station LTER, Antarctica, was added to the network supported by funds from Polar Programs and Environmental Biology divisions; Geographic Information Systems (GIS) working group analyzed the status of LTER Network technical supplements and assessed future technical needs; and Global Positioning Systems (GPS) units were acquired for shared LTER site use and GPS training provided for representatives from all sites.

1992 – The LTER Coordinating Committee, at the request of NSF, developed an 8-year vision ("LTER 2000") for the creation of a global environmental research network based upon approaches established in the LTER Program.

1993 – A second Antarctic site, McMurdo Dry Valleys, was selected for the LTER Network; the NSF commissioned a 10-year review of the LTER Program; the third LTER All Scientists Meeting was held at Estes Park, CO; an International LTER Summit at the Estes Park meeting led to the establishment of the International LTER (ILTER) Network, with Jerry F. Franklin (U.S. LTER Chair) as Steering Committee Chair; the LTER Network Internet (gopher) server was established at the Network Office; the LTER All-Site Bibliography, Core Data Set Catalog, and Personnel Database were developed and put online in searchable form; and the North Inlet LTER site was withdrawn, leaving 18 sites in the network.

1994 – In response to the 10-year review of the LTER Program, NSF conducted a special competition

Box 5. Augmented LTER Sites

In 1996, NSF began an experiment that involved augmenting two LTER sites at a funding level that was double the network standard. The two sites, North Temperate Lakes in Wisconsin and Coweeta in the southern Appalachian mountains, were selected based on competitive proposals [33]. The successful proposals contained significant commitments to involve social and economic sciences and plans for developing regional-scale research.

The increased funding gave these sites the opportunity to focus on complex interactions between humans and ecological processes across a range of scales and to make significant advances in understanding the spatial, temporal, and decision-making components of land use and land-use change, and to build regional, national, and international collaborations.

The site augmentation experiment led to several significant findings by the participating sites. For example, North Temperate Lake researchers found that the economically optimal phosphorus input to lakes is often far less than estimates based on assumptions that lakes are linear, equilibrium systems with no stochastic factors and no time delays. By calculating the net economic value of water quality (based on the economics of farming, value of housing near the lake, and the recreational economy derived from boating, fishing, etc.), the researchers showed that the economically optimal phosphorus loading (which maximizes net costs and benefits to society as a whole) was about one third the current loading rate of the lake. These analyses show that the total economic value (i.e., the net benefit from all uses of the watershed, including agriculture, lakeshore property values, fishing, and other recreation) generated by the Lake Mendota watershed would increase substantially if less fertilizer were used.

At Coweeta, a spatially explicit model of land-use change over a 40-year period (1950–1990) identifying physical and human factors and determining land-use patterns for representative areas across the region showed that land-cover changes were more frequent at lower elevations and near roads. Bird diversity declined with forest patch size, which in turn influenced plant community composition. Some plant groups (e.g., *Liliaceae* and *myrmecochores*) with diaspores dispersed by ants were scarce or absent in patches subjected to intensive past land use. Land-use history was more important than patch size in explaining variation in abundance and composition of seed-dispersing ants. Fish density and diversity, in particular, were more affected by upstream than streamside deforestation. The "legacy effect" and the relative importance of upstream process pointed the way toward large-scale and long-term restoration given the implication that localized efforts often had little effect.

The discovery of these dramatic effects of land-use patterns and environmental heterogeneity on populations and communities led the Coweeta LTER to begin a new 30-year study in 2000 of stream regions forecast to differ over time in type and risk of development.

for cross-site and international comparisons and synthesis; nine grants ranging from $109,353 to $200,000 were made to LTER and non-LTER sites in the United States, Ireland, Scotland, Costa Rica, Argentina, and Russia; NSF announced a special competition for augmentation of LTER projects (Box 5) for regionalization, comprehensive site histories, and increased disciplinary breadth; LTER established a World Wide Web site at the Network Office; the first International LTER (ILTER) Steering Committee meeting was held at Rothamsted, U.K.; and NSF signed Memoranda of Agreement with the U.S. Forest Service and the National Biological Survey to cooperate/collaborate in LTER Program research.

1995 – Jerry Franklin retired after 12 years of service as Chair of the Coordinating Committee and was replaced by James Gosz; LTER established a National Advisory Board; NSF announced 13 new awards for cross-site comparisons and synthesis at LTER and non-LTER sites; the LTER Publications Committee developed a plan for publication of Network research synthesis volumes; and NSF/DOE/NASA/USDA Joint Program Awards, Terrestrial Ecology and Global Change (TECO), were awarded to seven LTER recipients, including researchers at Bonanza Creek, Cedar Creek, Central Plains, Harvard Forest, H.J. Andrews, and Jornada.

1996 – The first LTER site synthesis volume (Palmer LTER) was published by the American Geophysical Union (AGU).

1997 – A special competition resulted in addition of two new urban LTER sites (Central Arizona Phoenix and Baltimore Ecosystem Study); the Network Office officially began operation from the University of New Mexico.

1998 – An NSF competition resulted in a former Land Margin Ecological Research (LMER) site (Plum Island Ecosystem) joining the network; the LTER Network signed a contract to produce a Science Synthesis Series with Oxford University Press; Schoolyard LTER Supplements ($15,000 per year to each site) were added to LTER grants.

1999 – NSF provided funding supplements to enhance Internet connectivity at LTER sites; the LTER Social Science Committee was created; the LTER Network Office, the National Center for Ecological Analysis and Synthesis, the San Diego Supercomputer Center, and University of Kansas collaborated on the "Knowledge Network for Biocomplexity"; and a synthesis volume, "Standard Soil Methods for Long Term Ecological Research," was published by Oxford University Press.

Major Milestones in the Third LTER Decade

2000 – Three new coastal sites joined the network (Georgia Coastal Ecosystem, Florida Coastal Everglades, and Santa Barbara Coastal); the fourth LTER (and first ILTER) All Scientists Meeting was held in Snowbird, Utah, in association with the annual meeting of the Ecological Society of America; and LTER entered into a collaborative relationship with the Organization of Biological Field Stations.

2001 – NSF conducted a 20-year review of the LTER Network; LTER celebrated its twentieth Anniversary; and the LTER Education Strategic Plan was published.

2002 – The first of what became an annual series of NSF-LTER Mini Symposia was held in Washington, DC; the LTER Network Information System Advisory Committee (NISAC) was formed; and the LTER Strategic Plan ("LTER 2000–2010: A Decade of Synthesis") was published.

2003 – The Cooperative Agreement for the LTER Network Office at the University of New Mexico was renewed; the fifth LTER All Scientists' Meeting was held in Seattle, Washington, in association with the Estuarine Research Federation; a Special Issue of *BioScience* focused on the Long-Term Ecological Research Network; the LTER Coordinating Committee approved a formal set of bylaws for the LTER Network; and the U.S. International Committee was formed.

2004 – The first LTER children's book, "My Water Comes from the Mountains," was published; two new sites (California Current Ecosystem and Moorea Coral Reef) joined the LTER Network; and the LTER Network received a grant from NSF to conduct network-level strategic planning.

2005 – The first LTER Graduate Student Collaborative Research Symposium took place at Andrews Experimental Forest; and the LTER Network Office "Strategic Plan" and "Implementation Plan" were published.

2006 – Jim Gosz stepped down after 10 years as Chair of the LTER Coordinating Committee and was replaced by John Magnuson; the Sixth LTER All Scientists' Meeting was held at Estes Park, CO; and the LTER Coordinating Committee approved a new LTER governance structure consisting of a Science Council and an Executive Board (Box 6).

2007 – Phil Robertson was elected Chair of the LTER Executive Board and Science Council; the "Decadal Plan for LTER," incorporating an integrated research plan, a description of the EcoTrends project, a Strategic Plan for Education, a Strategic Plan for Cyberinfrastructure, a new governance plan, and the "Integrative Science for Society and the Environment" document, was published; and "Principles and Standards for Measuring Primary Production" was published as part of the LTER series by Oxford University Press.

2008 – The LTER Network and the National Phenological Network signed a MOU for cooperation in phenological monitoring and assessment.

2009 – The seventh LTER All Scientists Meeting was held at Estes Park, CO; the LTER Network Office core funding was renewed and a separate award was made by NSF to facilitate synthesis and the development of network cyberinfrastructure.

2010 – The LTER Network received the Distinguished Scientist Award from the American Institute of Biological Sciences (AIBS); NSF initiated a 30-year

Box 6. Governance Structure

The Network is governed by bylaws enacted in 2003 by the *Coordinating Committee*, at that time the governing body of the LTER Network. The bylaws established a new governance structure consisting of an elected *Chair* and an *Executive Board* comprising nine rotating site representatives and one non-voting member selected to provide expertise on information management. Site representatives are the lead principal investigators of each LTER site. The Chair and the *Executive Director* of the LTER Network Office are ex officio members of the Executive Board. The *Science Council*, with a membership that includes two representatives from each site and the chairs of each Standing Committee, establishes the scientific direction and vision of the LTER Network. The voting membership of the Science Council (the 26 lead principal investigators from each site) reserves ultimate authority for decisions affecting the network. Ten *Standing Committees* (Climate, Communications, Education, Graduate Students, Information Management, International, Network Information System, Networks Coordination, Publications, and Social and Economic Science) support and inform the governance process. A *Network Office*, (see Box 2) funded separately by the National Science Foundation, facilitates research, education, information management, and governance activities (Fig. 5).

review of the LTER Program; and LTER created a Communications Committee and a Networks Coordination Committee.

2011 – Scott Collins was elected Chair of the LTER Executive Board and Science Council.

The LTER Network Today

Twenty-six research sites and a central coordinating office constitute the LTER Network at present, and more than 1,500 scientists are involved in research at these sites. The annual budget of the LTER program approaches $30 million (Fig. 6). The Network includes a wide range of ecosystem types spanning broad ranges of environmental conditions and human domination of the landscape. The geographic distribution of sites ranges from Alaska to Antarctica and from the Caribbean to French Polynesia and includes agricultural lands, alpine tundra, barrier islands, coastal lagoons, cold and hot deserts, coral reefs, estuaries, forests, freshwater wetlands, grasslands, kelp forests, lakes, open ocean, savannas, streams, and urban landscapes. Collectively, the sites in the LTER Network provide opportunities to contrast marine, coastal, and continental regions, the full range of climatic gradients existing in North America, and aquatic and terrestrial habitats in a range of ecosystem types. All sites are sufficiently large to incorporate moderate to large landscape mosaics, and most sites include human-manipulated as well as natural ecosystems. Most sites embody considerable within-site variability in habitats and ecosystem processes and attempt to characterize this variability in the context of broad regional gradients covering hundreds of kilometers.

In accordance with the factors driving the development of long-term ecological research in the United States, the LTER Network has adopted a central, organizing intellectual aim: to understand long-term patterns and processes of ecological systems at multiple spatial scales. To achieve this aim, the LTER Network focuses on six interrelated goals [7]:

Understanding: Gaining ecological understanding of a diverse array of ecosystems at multiple spatial and temporal scales.

The mission of the LTER Network begins with research based at individual sites, each of which has a unique theme. This site-based focus has allowed for key scientific advances at each of the sites, while the common focus on long-term research in a diverse array of ecosystems and landscapes has facilitated broad comparisons and syntheses across sites. Together the network of sites covers a wide range of subjects at multiple temporal and spatial scales.

Synthesis: Using the network of sites to create general ecological knowledge through the synthesis of information gained from long-term research and development of theory.

The products of LTER research extend beyond the accumulation of knowledge about diverse, individual ecosystem types. At a higher level, synthesis of this site-based knowledge across the network provides the broader scientific understanding from which new theory is derived and general applications can be developed.

Long-Term Ecological Research Network. Figure 5

Long-Term Ecological Research Network. Figure 6
Growth of the LTER Network

Information Dissemination: Creating well-designed, documented databases that are accessible to the broader scientific community.

Long-term research demands long-term data. The creation, curation, and dissemination of long-term databases are needed to assure that the data resources

needed by researchers will continue to be available. These databases must include the additional information required to interpret data (i.e., metadata) as well as the data themselves. By adopting policies that promote the timely sharing of data (both inside and outside the LTER Network), the data can be used in a variety of ways not anticipated by the original collector such as regional, national, and global syntheses, thus providing a resource for the broader scientific community.

Legacies: Creating a legacy of well-designed and documented long-term observations, experiments, and archives of samples and specimens.

Many ecological phenomena change at decadal to century and longer time scales, and it is essential to maintain experiments and observations across periods appropriate to the questions addressed. The orderly transfer of experiments and interim results from one generation of scientists to the next requires a research design and setting that allows for multiple samplings (some unanticipated), long-term protection from competing uses, and meticulous documentation of experimental protocols. Also essential is a means to store protocols and observations in a manner that is secure and consistently accessible to the scientific community for use in syntheses and cross-site comparisons (both inside and outside the LTER Network).

Training: Developing a cadre of scientists who are equipped to conduct long-term, collaborative research to address complex ecological problems.

One of the major lessons from the first 30 years of LTER has been that success both within sites and within the network requires a nontraditional approach to ecological research. This approach is characterized by a commitment to long-term measurements that may yield only a few useful initial results but that are essential to understanding long-term change, by a willingness to work as part of large teams that may have priorities that are different than one's own, by a desire to interact closely with others in order to share ideas and data, and by the need to develop a broad interdisciplinary perspective. Disseminating this approach through the involvement of graduate and undergraduate students, postdoctoral and international scientists, and K-12 educators, students, and the general public can ensure the success of long-term ecology in the future.

Outreach: Providing knowledge to the broader ecological community, general public, resource managers, and policy makers to address complex environmental challenges.

Humanity faces increasingly numerous and serious environmental problems that range from local to global in extent, and that must be tackled by institutions at local to international scales. The LTER Network and emerging ILTER networks provide the most comprehensive and diverse system of sites for ecological observations on the globe, and research of the LTER Network has repeatedly demonstrated the ability of long-term ecological science to address these environmental challenges. Increasingly, LTER research is finding applications in the work of federal, state, and local agencies that manage environmental resources. The synoptic and detailed knowledge of individual LTER sites, and the opportunities for multidimensional comparisons among sites, also represents significant opportunities for other disciplines including social sciences, earth sciences, and basic biological sciences that must be pursued. Finally, knowledge from this breadth of views permits us to identify and anticipate new issues and challenges, test existing ideas about causation, and help provide the science that underpins the processes of open, participatory, and forward-looking decision making.

Achievements of the LTER Network

- "At each of the Network's 26 sites we know an extraordinary amount about organisms and processes important at the site, about the way the site's ecosystems respond to disturbance, and about long-term environmental change. A growing number of cross-site observations and experiments is also revealing much about the way that key processes, organisms, and ecological attributes are organized and behave across major environmental gradients. In total, research in the LTER portfolio is contributing substantially to both our basic knowledge of ecological interactions and our ability to forecast change and to test ecological theory." (p(i), [34])

LTER's long-term research and monitoring has led to important new discoveries and had a transformative effect on science and society. Hobbie [35] listed the benefits resulting from the existence of the network: value added to research sites in the network because of long-term stability; value added to ecological science

because long-term sites provide ecology with sustained intellectual attention to fundamental ecological issues; LTER data bases, which are important resources for the broader scientific community; cross-site synthesis, enabling hundreds of scientists to ask similar questions in a wide variety of habitats and increasing the possibilities for creative breakthroughs from interdisciplinary collaboration; education and training of teachers and students as an integral part of research programs; cooperative research with government agencies (e.g., in national parks, wildlife refuges and reserves, and experimental forests); contributions to society through advice on public policy and environmental management; and the establishment of an international LTER Network that now numbers 40 countries, facilitating collaboration in addressing environmental challenges in different parts of the world.

In 2010, the LTER Network received the Distinguished Scientist award from the American Institute of Biological Sciences for its contributions to the biological sciences. LTER research is featured in two of NSF's "Sensational 60" transformative scientific discoveries or advances [36]. Results from LTER research are embodied in over 10,000 peer-reviewed publications [35], a book series from Oxford University Press, and summaries on network (www.lternet.edu) and site web sites. Since 1993, the LTER research model has been adopted by 40 other member countries of the International Long Term Ecological Research Network.

Research Progress in achieving the LTER Mission begins with the work of individual scientists, students, and educators at the 26 LTER sites. It is their work at the site level that forms the foundation of knowledge, data, observational and experimental legacies, and training that will ensure a lasting impact of the overall LTER program. Data and knowledge gained from intensive field experience are also key to development of syntheses of site-level information into models that allow prediction of long-term change and responses to human and other disturbances. Site-level synthesis activities often lead to new insights that feed back to affect the future course and evolution of site-level research.

Network infrastructure also promotes and facilitates cross-site and regional analyses, leading to larger-scale syntheses and to development and testing of ecological theory. In this work, the maintenance of a network database and protocols for data discovery and acquisition are particularly important. These efforts add to the basic body of scientific knowledge of long-term, large-scale ecological phenomena and, because students are deeply involved both at the site level and in intersite and network-level syntheses, they help to increase the numbers of people with appropriate expertise in both research and environmental problem solving.

Ultimately, both site and network-level activities feed back to the development of scientific capital, which includes well-trained scientists, a well-informed citizenry, and the basic data and understanding that underpin them. This accumulation of scientific capital also leads to new research and new applications of LTER research, including new forms of support for both research and education. Growth of scientific capital also includes interactions with new scientific disciplines, leading to expansion of the scope and applications of LTER research.

Research at LTER Sites The LTER Network comprises sites chosen competitively on the basis of research excellence, quality and duration of existing data sets, and strength of the commitment to long-term research and site security. The 26 sites that constitute the network at present represent a wide variety of research emphases and approaches. As part of their commitment to the LTER program, each site conducts a series of measurements and experiments directed toward the understanding of the five core areas as well as studies addressing ecological issues specific to the site. The most common scientific approaches include observation, experimentation, comparative analysis, retrospective study, and modeling, although emphases differ among sites. A sampling of key research results from LTER sites provides an idea of the potential impact of LTER research.

The Ecosystem Value Of Dead Wood – H. J. Andrews LTER scientists revealed the importance of dead trees to diversifying animal habitat and sustaining the flow of vital nutrients in forests and streams by tracking how fallen and standing deadwood changes as forests age. These studies profoundly influenced forest management by prioritizing the retention of dead wood in forests and streams.

Arctic Warming – Arctic LTER scientists discovered how Arctic warming is increasingly thawing frozen ground (permafrost), creating hot spots of erosion, nutrient release into rivers, and decomposition of ancient organic carbon. This information is essential for managers and policymakers grappling with how to mitigate and adapt to future climate change.

Fire and Climate – Through long-term studies of fire cycles and their links to climate, Bonanza Creek scientists have documented an increase in fire severity brought on by climate warming that will likely shift the Alaskan boreal forest from a spruce- to a broadleaf-dominated landscape.

New Climate Pattern – Long-term observations allowed California Current Ecosystem scientists to define a new climate pattern called the North Pacific Gyre Oscillation (NPGO), which links physical ocean changes, such as fluctuations in salinity and nutrients, with biodiversity and ecosystem processes in the eastern North Pacific. This climate pattern may affect marine ecosystems around the world.

Biodiversity Matters – Cedar Creek scientists discovered that the number of plant species in an ecosystem – its biodiversity – has a profound and surprisingly strong effect on ecosystem function. Long-term experiments have shown that ecosystems with greater plant species diversity are more productive and stable.

Integrative Research – Central Arizona-Phoenix scientists spearheaded efforts to integrate ecological and social research in urban ecosystems. Such interdisciplinary research has changed the way scientists and citizens perceive the natural environment in cities, transformed environmental education at all levels, and informed problem solving in cities.

Future Nitrogen Cycling – Drawing on two decades of research, Coweeta researchers discovered that warmer temperatures increase peak nitrate loading to forest streams during the growing season. These findings suggest that climate warming will triple the nitrogen export from forests, reducing water quality and long-term forest productivity.

Productivity Paradox – Florida Coastal Everglades scientists revealed how human-induced nutrient enrichment in the Everglade and Caribbean wetlands affect the "productivity paradox" in which an extraordinarily high level of algal growth supports far fewer aquatic animal consumers than expected. Understanding this dynamic is critical to the restoration of the Everglade ecosystems.

Sea-Level Rise – Georgia Coastal Ecosystem scientists predicted how rising sea levels will impact coastal marshes and reduce the benefits they provide society, such as clean water and fish habitat. Analyses have shown that new marshes created by rising waters do not fully offset the loss of existing marshes.

Legacies Shape Ecosystems – Using its century-long studies, Harvard Forest scientists have documented the persistent influence of human and natural history in shaping modern forest ecosystems. Ancient land use practices and prior forest conditions continue to influence a forest's potential to grow trees, respond to disturbance and stress, and support diverse plants and animals.

Shifting Songbirds – Hubbard Brook scientists have produced the longest continuous songbird record in North America and discovered that changing habitat, land use practices, and climate in eastern forests, tropical forests, and migratory routes drive the abundance of these beloved forest musicians.

Grassland Tipping Points – Jornada LTER scientists discovered that grasslands, shrublands, and other ecosystems have "tipping points," where dramatic and rapid changes can occur once certain thresholds are reached. A better understanding of these thresholds is paramount to management and protection of grasslands and other ecosystems.

Agriculture and Climate Change – Kellogg Biological Station researchers discovered and quantified how different crop management practices can interact to provide novel opportunities for greenhouse gas mitigation by agriculture. These discoveries inform agricultural greenhouse gas policies worldwide.

Sensitive to Change – Using long-term data on plant productivity and novel experiments to manipulate rainfall, Konza Prairie scientists demonstrated that grasslands are among the most sensitive ecosystems to changes in the water cycle. This research helps forecast the impact of climate change on the carbon balance of individual plants to whole ecosystems.

Tropical Carbon Cycling – Luquillo Experimental Forest scientists discovered that carbon cycling in tropical forests is highly sensitive to climate. Relatively small increases in temperature can decrease the ability of tropical forests to store carbon recently

captured by photosynthesis, thus accelerating climate change.

Chain Reaction – McMurdo Dry Valleys scientists documented how even small variations in climate can drive major changes in polar ecosystems: Seemingly slight changes in temperature can set off a cascade of magnified responses that affect stream flow, nutrient cycling, and biodiversity.

Diversity Matters – Coral reef ecosystems are highly sensitive to disturbances and climate change. Moorea Coral Reef research documented how genetic and species diversity among corals and their symbionts helps corals to rapidly adapt to changing environmental conditions such as warming seawater and ocean acidification.

Early Warning Signs – Niwot Ridge research indicates that alpine ecosystems provide important early warning signs of global climate change. Alpine plants and animals survive on the razor's edge of environmental tolerances, making them more sensitive to changes in climate than downstream ecosystems.

Tracking Ice Cover – By synthesizing long-term records of lake and river ice cover throughout the Northern Hemisphere, North Temperate Lake scientists discovered long-term climate-induced reductions in ice cover on freshwater ecosystems over the past 150 years.

Penguins and Climate Change – Palmer Station scientists have documented a 75% reduction in Adélie penguin populations since 1980 and determined the cause to be altered cloud cover, winds, snowfall, sea ice cover, and other climate changes.

Tipping Points – Plum Island Ecosystem scientists discovered regionally specific "tipping points" beyond which marshes can no longer keep up with rising sea levels, and that human alteration of watersheds can either enhance or compromise a marsh's ability to survive in the face of rising sea levels.

Underwater Forests – Giant kelp provides critical food and shelter for a wide diversity of economically important organisms. An interdisciplinary team of Santa Barbara Coastal scientists discovered that kelp plants disperse their reproductive spores over surprisingly great distances, furthering our understanding of how these important ecosystems establish and survive.

Climate and Disease – Long-term observations and experiments by Sevilleta LTER scientists revealed an important link between human hanta virus outbreaks and the population dynamics of small mammals in the southwestern United States as affected by changes in climate systems such as El Niño. The discipline of the ecology of infectious diseases that this research helped to establish is now a transformative area of ecological research.

Plague and Prairie Dogs – For over two decades, Short Grass Steppe scientists have observed black plague spreading through populations of the black-tailed prairie dog, an endangered species candidate. The effects of the resulting die-offs ripple through other populations including other rodents, flowering plants, pollinators, and large herbivores.

Dynamic Coastal Landscapes – By tracking long-term shifts in land cover on undeveloped coastal barrier ecosystems, Virginia Coast LTER scientists have learned how sea-level rise and storms interact to create a highly dynamic landscape. While the locations of lagoons, marshes, and other coastal ecosystems have changed over time, they have not experienced a net reduction in the area they cover.

Cross-Site Research and Synthesis In addition to transformative site–based research, LTER scientists conduct synthetic studies focused on general ecological principles underlying diverse ecosystems [22, 26, 35, 37–47]. Johnson et al. [21] demonstrated the evolution of the LTER program from a collection of research sites with common goals to a highly connected research network. A few examples illustrate the breadth of LTER cross-site research.

EcoTrends – The EcoTrends Project [47] is a collaborative effort among state and federal agencies and institutions in the United States to make long-term ecological data easy to access, analyze, and compare within and across sites (see http://www.ecotrends.info). The project is designed to promote and enable the use and synthesis of long-term data to examine critical trends (e.g., climate, land cover, and habitat availability) in the Earth's ecosystems. In addition to ecological data collected by participating sites, the EcoTrends database includes ancillary data from other sources. For example, LTER investigators obtained human population and economic data from 1790 to 2000, which was one of the four types of data being synthesized in the EcoTrends Project. The "Human

Population and Economy" dataset contains over 200 separate variables suitable for describing changes in population and economic structure since the end of the eighteenth century. The dataset was collected for each of the more than 250 counties associated with the 21 continental North American LTER sites plus the Luquillo site in Puerto Rico. These datasets, tools, and information are available to anyone who would like to view trends in ecological variables for one or multiple sites or pursue additional statistical analyses of within-site and cross-site comparisons.

Climate Database (CLIMDB) and Hydrology Database (HYDRODB) – LTER sites have generally followed established LTER Climate Committee guidelines (see [29]) for collecting baseline meteorological data. Standardized measurements provided a basis for coordinating meteorological measurements at two or more sites and enabled intersite comparisons, but access to comparable datasets from multiple sites was often problematic because most sites, while making climate data accessible online, displayed them in different formats and aggregated them using different methods. Similarly, sites that conducted long-term hydrologic measurements needed to establish access to their long-term datasets for streamflow, precipitation, and ambient air temperature, in addition to the hydrologic data. LTER developed ClimDB and HydroDB in response to the science-based need for standardized measurements, format, and aggregation of these data. LTER sites, along with USGS, and USDA Forest Service sites, contribute climate (http://www.fsl.orst.edu/climhy/) and hydrological (http://www.fsl.orst.edu/hydrodb/) data, which are stored in centralized servers that provide open access to long-term meteorological and stream flow records from these research sites.

Long-Term Intersite Decomposition Experiment Team (LIDET) – Sixteen LTER sites participated in a 10-year, 28-site experiment to test the effect of substrate quality and macroclimate on long-term decomposition and nutrient dynamics – particularly the degree to which these two factors control the formation of stable organic matter and nitrogen after extensive decay. Reciprocal litter transplants of 27 species were conducted at sites in North and Central America. Decomposition rates were strongly affected by substrate quality, but climate also resulted in strong and consistent effects [25]. Large-scale patterns were better explained by variables including both moisture availability and temperature. In general, roots decomposed more slowly than leaves, but ratios of aboveground to belowground decomposition rates varied across ecosystem types. Predictions of decomposition rates were possible using uncomplicated models based on litter quality and climate, but ecosystem-specific factors also contributed to observed differences (see http://andrewsforest.oregonstate.edu/research/intersite/lidet.htm for more information).

Lotic Intersite Nitrogen Experiment (LINX) – The Lotic Intersite Nitrogen Experiment was a collaborative study of nitrogen cycling in streams involving simulation modeling, field tracer (^{15}N) additions, and intersite comparison. The central hypothesis was that the considerable variability among streams in uptake, retention, and cycling of nitrogen is controlled by key hydrodynamic, chemical, and metabolic characteristics that determine water retention, degree of nitrogen deficiency, and energy flow through food webs in stream ecosystems. LINX I ran from September 1996 through August 2001 and resulted in 26 publications, 7 theses and dissertations, and 69 presentations. The study demonstrated that the smallest streams had the highest uptake of inorganic nitrogen, and that small streams were potentially significant sources of atmospheric nitrogen via nitrification.

LINX II was a 5-year project that began in September 2001 and ended in 2006. Data from tracer experiments across 72 streams and eight regions representing several biomes showed that biotic uptake and denitrification were less efficient at removing stream nitrate in streams with high nitrate concentrations. As a result, high nitrate streams export a disproportionate amount of nitrate to receiving waters. In addition, these patterns suggest that small streams become less important as nitrate sinks as nitrate concentration increases [48].

In addition to the specific cross-site and intersite research mentioned above, LTER sites also participate in numerous long-term interdisciplinary and multi-site syntheses with both LTER and non-LTER organizations. These include studies of above- and belowground productivity, carbon dioxide (CO_2) and climate change, biodiversity, disease control, microbial ecology, remote sensing, and geographical information systems, the

adsorption of trifluoroacetate (TFA) in soils, among others.

National and International Networking – As a global leader in long-term and broad-scale ecological research, the LTER Network establishes linkages with existing and developing long-term ecological research programs in the United States and abroad. These relationships range from exchanges at the individual scientist and site research program levels, to participation in national and international meetings, to global-scale research planning and collaboration.

Nationally, LTER develops innovative partnerships with leading ecological research organizations and synthesis centers; facilitates the advancement of current ecological science and innovative research technologies; develops strong multidisciplinary science and public education programs; and pursues a multi-agency approach to develop databases of long-term research in key biomes and along major gradients.

Internationally, LTER assists in the establishment of networks for long-term ecological research worldwide; creates opportunities for collaboration between US and International LTER sites and networks; develops and operates a communication and data-sharing system among an international network of sites; facilitates the establishment of a global network of environmental research sites; and participates in other international scientific efforts.

Education Education and outreach efforts are integral aspects of the LTER program. As a network of sites with a preponderance of academic scientists, graduate and undergraduate education is central to the goals of the network. Students at both graduate and undergraduate levels are routinely engaged in collecting LTER data, performing experiments, and analyzing results. This participation forms an important part of their educational experience, and hence education and research are highly integrated in most LTER programs. The network has many examples of former undergraduate students that have become research scientists in the LTER program.

In addition, LTER provides a unique opportunity to address the educational needs of teachers and students from grades K-12. As a long-term program, LTER has the potential to provide continuous opportunities for students to participate and learn throughout their entire academic life.

The LTER Network has adopted a strategic vision for education and outreach with three components. The first component addresses the structure needed to enable LTER research to have a public impact. This structure includes leadership within the network, a distributed organization that provides resources for sites to implement education programs at the local level, and cyberinfrastructure that enables broad collaboration among local education projects and between researchers and educators. The second element of the LTER vision for education establishes the goal of conducting programs in research and development that address environmental science literacy by respecting and including the diverse perspectives that exist within the LTER Network. The final aspect of the LTER vision addresses inclusion of key constituent groups, including K-12 teachers and administrators, undergraduate and graduate students and professors, and end citizens active in LTER communities.

K-12 Schoolyard LTER Program In 1998, LTER formally expanded its education efforts to include K-12 students and teachers, mainly through the Schoolyard LTER (SLTER – http://schoolyard.lternet.edu/) program, which is funded through supplements by NSF's Division of Environmental Biology (DEB). The SLTER approach emphasizes the connection to local communities, for which an LTER site can serve as a "schoolyard" for understanding ecology and environmental science. The sites design their own programs in relation to the ecological research conducted at the site and the particular needs and resources of the local school district and community ([49], http://schoolyard.lternet.edu/LTEREduHandbook.pdf). SLTER funds support a wide range of education activities, including field trips and lab work for students, teacher professional development workshops, teaching supplies, community outreach, and program and research coordination. The schoolyard approach is particularly consistent with the development of empathy for their local environment ("Environmental Empathy") as discussed by Sobel [50] as a basis for teaching elementary age students. All the 26 LTER sites participate in the SLTER program.

As the SLTER program matured, LTER scientists devised the idea for a Children's Book Series to supplement SLTER activities – thus using children's science literature to overcome "ecophobia" while fostering environmental empathy [51]. The series currently includes three titles: "My Water Comes From The Mountains" by Tiffany Fourment (Note: the title has since been modified to reference specific mountains, e.g., "My Water Comes From The Rocky Mountains" and "My Water Comes From The San Juan Mountains"), "The Lost Seal" by Diane McKnight; and "Sea Secrets" by Mary M. Cerullo and Beth E. Simmons. Each book is richly illustrated with scenes derived from the story, with many artworks and sidebar comments by elementary school children.

Graduate and Undergraduate Education The LTER science community includes academic and government scientists and educators, graduate and undergraduate students, and professional staff. The research conducted at the sites is diverse, encompassing all aspects of ecology and ecosystem science, as well as investigations in atmospheric science, hydrology, and geomorphology. As centers of excellence in ecological research, LTER sites hosted by universities, government agencies, and nonprofit research institutions also provide important training grounds for the next generation of scientists and leaders. LTER offers opportunities for graduate and undergraduate training and education. Many undergraduate and graduate students are supported directly from LTER awards each year and others use LTER facilities and equipment in support of their research programs. In addition, the LTER Network, through its association with other networks worldwide, provides opportunities for the international interchange of students and faculty.

In addition to typical university-based training, many LTER sites are involved in NSF-funded Integrative Graduate Education and Research Traineeship (IGERT) programs, and serve as hosts for Undergraduate Mentoring in Environmental Biology (UMEB) and Research Experience for Undergraduates (REU) site activities. The programs integrate field and laboratory techniques with education, providing the students with deeper understanding of the scientific process in ecology.

Most LTER sites or their home institutions participate in the REU and UMEB programs, which offer opportunities for students at both LTER and non-LTER institutions to work with LTER scientists. Participating sites fund REU students through separate grants and supplements or out of project funds. REU students receive stipends and course credit and work closely with scientist mentors on ongoing site research programs or specially designed projects. The UMEB program provides stipends to minority students during the summer and academic year to undertake independent research projects in environmental biology under the direction of departmental faculty. Students in the program come from a wide variety of disciplines including chemistry, geophysics, and biology. Some sites provide similar opportunities through private foundations and other sources.

LTER Education in the Future The LTER Network has adopted the goal of advancing the theory and practice of ecological and environmental education at all levels and in all areas of LTER expertise. The LTER sites and network are uniquely poised to promote education at the program, institution, state, and national levels. This work builds on, and is linked closely to, LTER scientific expertise in its five core research areas and its long-term, comparative approach. LTER education addresses some of the most important but vexing objectives for ecological and environmental education; that is, it uses outdoor, inquiry-based teaching and learning to build ecological literacy; it creates effective strategies for interdisciplinary and collaborative learning about ecology and it teaches about local ecosystems while fostering an understanding of distant ones as well. Strategic objectives for future LTER education programs [2] include:

1. Expanded resources for education and outreach at both site and network levels by developing new funding sources and improving coordination with existing education and outreach programs
2. Increased participation by LTER sites in education and outreach through collaboration, coordination, training, and exchange of best practices among sites
3. Preparation and dissemination of new instructional materials designed and developed through strategic partnerships with constituent organizations, with

particular attention to the needs of traditionally underrepresented groups
4. Development of metrics to evaluate and guide education and outreach activities at site and network levels
5. Increased use of appropriate cyber technologies to improve indication among partners and to disseminate educational and outreach materials more effectively
6. Regular adaptive assessment by external evaluators to monitor progress of LTER education and outreach programs and to design new approaches when necessary

Data and Information Long-term research and synthesis demands the long-term stewardship and ready accessibility of data. The creation, curation, and dissemination of long-term databases are needed to assure that the data resources needed by researchers will continue to be available. In addition, by adopting policies that promote the timely sharing of data (both inside and outside the LTER Network), scientists can use the data in a variety of ways not anticipated by the original collector, including for regional, national, and global syntheses, thus providing a rich resource for the broader scientific community [2].

LTER has led the ecological community in developing protocols and practices for documenting, curating, and sharing data. The strategic goals for LTER information management are (1) to provide sources of high-quality, well-documented, and error-checked data at each site that support local science, stimulate synthesis and the creation of new knowledge, and facilitate transformative network-wide research at broad scales; (2) to improve existing data practices and information management systems at sites to make them uniformly easy to use, sustainable, and consistent with LTER protocols; (3) to develop a central network-level data discovery and integration platform comprising databases and servers connected through web services for single-portal data publication, discovery, and access; (4) to improve information flow between LTER and other networks; and (5) to evaluate recent developments in computer science, information technology and design, cybersecurity, community standards, and communication and collaboration technology for potential application in LTER Network and site information management.

The recent proliferation of long-term collaborative research programs has created a parallel need for scientific information systems that allow data, information, and knowledge to flow across disciplinary and cultural boundaries [52]. Scientific information systems expand the potential for scientific inquiry and are leading to a paradigm shift in biology [53] most evident to date in the genomic community [54]. Other disciplines, including ecology, are primed for similar dramatic changes driven in part by new tools and approaches to managing data. The success of long-term studies is measured both on the generation of new knowledge and the creation of data and information that will facilitate subsequent studies.

Future Directions

LTER is moving increasingly toward research that integrates ecological and social sciences (Fig. 7), having realized that fundamental questions related to the services that society receives from ecosystems, how these services are perceived, how perceptions affect behavior, and how behavioral changes affect ecosystem form and function are central to understanding the sustainability of ecosystems on which society depends. By blending ecological and social science theories, methods, and interpretations, LTER is better able to understand and forecast environmental changes at a time when no ecosystem on Earth is free from human influence. The *Decadal Plan for LTER* [34] laid out a plan for integrated, network-level research to address crucial long term social-ecological questions in three thematic areas: (1) land and water use change – the dynamics of urban, exurban, and working systems; (2) climate change, variability, and extreme events; and (3) nutrient mobilization and species introductions. These questions are interdisciplinary in nature, and were developed after extensive discussions and consultations among teams of biophysical and social scientists, educators, and

Long-Term Ecological Research Network. Figure 7
Integrated science for society and the environment, a framework for future LTER research (From Collins et al. [55])

information managers. The questions are also multi-scale, and require observations and experiments at multiple sites to test hypotheses at scales ranging from regional to continental.

In fact, LTER is uniquely positioned to address these questions for a variety of reasons related to their long-term nature, the geographic distribution of network sites, the core strength of the network's biophysical science, its considerable and growing strength in the area of coupled human-natural systems, and its commitment to K-12 education and leadership in environmental cyberinfrastructure. Nevertheless, LTER recognized that it will require new long-term social-ecological observations, experiments, and modeling to address these questions effectively; advanced environmental cyberinfrastructure to collect, store, retrieve, visualize, and integrate the resulting complex data streams; partnerships with other environmental observatory networks to achieve this integration and facilitate synthesis; and education initiatives to train the next generation of environmental scientists to address transdisciplinary issues, and to enhance environmental literacy among the public.

Specific details of how the Decadal Plan's goals are to be achieved are constantly being worked out by Network science, education, and cyberinfrastructure teams, who identify individual questions, design observations, experiments, and modeling activities to address them, and the corresponding education

and cyberinfrastructure needs for the resulting transdisciplinary research initiative. Science teams are presently developing four projects to advance the goals of the LTER Decadal Plan. The first of these projects is an effort to develop future scenarios to understand the vulnerability and resilience of regional landscapes to climate and land use change. Vulnerability to future climate change is also the theme of a second working group that will examine the affects of sea-level rise, increased storm surge, ocean acidification, and increases in water temperature, loss of sea ice, and changes in fresh water inflows on coastal LTER sites. Another working group is developing an experimental approach to evaluate the sensitivities of inland social-ecological systems to climate change to be conducted on a continental scale. Finally, a fourth group will examine how changes in the global cryosphere will affect ecosystem services such as planetary cooling, sea-level regulation, carbon storage, soil insulation, and water storage. Together, these four developing projects reflect the future direction of the LTER program.

Glossary

Gap The physical clearance between a Maglev vehicle and the guideway it travels along.

Guideway The structure that holds Maglev vehicles as they travel. Guideways can be elevated above the local terrain, or on-grade, depending on the design, need for isolation from the local surroundings, and other factors.

Maglev (magnetic levitation) Transport of vehicles that are magnetically levitated above a guideway and magnetically propelled along it.

Magnetic Induction The generation of induced current in a conducting loop by the movement of a magnet past it.

Magnets, electromagnetic The generation of a magnetic field by a current in a loop of conductor, usually wound around an iron core to increase the strength of the magnetic field.

Magnets, permanent A physical object that is the source of a magnetic field, without the need for an electric current to produce the field. The movement of orbiting electrons in the atoms of the permanent magnet is locked in place to create the magnetic field.

Magnets, superconducting The generation of powerful magnetic fields from a loop or loops of zero electrical resistance superconducting wire, usually wound as an air core magnet without iron.

Superconductors Materials that when cooled below a transition temperature completely lose electrical resistance. They can carry very large currents at very high current densities, hundreds of thousands of amps per square centimeter of cross section, indefinitely without any decay in their current and without any voltage being applied to them.

Definition of the Subject and Its Importance

Maglev (magnetic levitation) is the first new mode of Earth-based transport since the invention of the airplane. Maglev vehicles are magnetically levitated and propelled along a guideway, with no mechanical contact and friction, their speed limited only by atmospheric drag. In evacuated tunnels, Maglev vehicles can potentially reach orbital speeds of 8 km/s (18,000 mph). Traveling in the atmosphere, Maglev vehicles have reached 580 km/h (361 mph).

Maglev vehicles have no engines, do not burn oil or other fuels, do not emit pollutants and greenhouse gases, and are quiet, with no rail or engine noise. They are propelled by the interaction between AC currents in the guideway and the magnets on the vehicle. The speed and position of Maglev vehicles on the guideway is determined by the frequency of the AC current that propels them. The distance between individual Maglev vehicles on the guideway can be designed to always remain constant, regardless of what conditions the different vehicles encounter, that is, up or down grades, curved guideways or straight, head or tail winds, etc. The individual vehicles are not

Robert A. Meyers (ed.), *Encyclopedia of Sustainability Science and Technology*, DOI 10.1007/978-1-4419-0851-3,
© Springer Science+Business Media, LLC 2012

controlled by on-board engineers. Instead a central traffic control center views the entire guideway in real time to detect potential hazards, controlling the location and speed of all vehicles by means of the frequency of the AC propulsion current fed to the energized block of guideway that each individual vehicle travels on.

Maglev vehicles can travel as individual single units on the guideway, or during high levels of traffic, can be coupled together to form multi-vehicle consists. Each vehicle is individually propelled by the AC current applied to the energized block of guideway the vehicle, or the multi-vehicle, consist is traveling on.

There are two types of Maglev: electromagnetic and electrodynamic. In electromagnetic Maglev the vehicles are equipped with conventional electromagnets in which a DC current winding energizes an iron structure to create a strong magnetic field. The vehicle's electromagnets are positioned underneath two iron rails attached to the guideway. The magnetic force between the vehicle's electromagnets and the guideways iron rails located above them levitate the vehicle.

Electromagnetic Maglev has three major limitations. First, its magnetic suspension is inherently unstable. As the vehicle electromagnets move closer to the iron rails above them, the attractive force automatically increases. To prevent a crash, the DC current in the vehicle's electromagnets must be reduced by a servo control system that operates on a very fast time scale, that is, thousandths of a second. The servo control system thus continuously adjusts current to maintain a safe gap between the vehicle and the guideway. The second limitation is that to keep the DC magnet power required to levitate the vehicle at an acceptable level, the gap between the vehicle and guideway must be very small, on the order of 1 cm (3/8 in.). This requires a very precise and high cost guideway. The third limitation is that the lifting capability of the Maglev vehicle is small, because of the heavy magnet and power system weights.

The second type, electrodynamic Maglev, uses permanent magnets on the vehicle, not electromagnets. Instead of having iron rails on the guideway, electrodynamic Maglev uses ordinary aluminum loops that are located beneath the vehicle's permanent magnets, not above them. As the Maglev vehicle moves along the guideway, its magnets induce currents in the aluminum loops. These induced currents magnetically interact with the vehicle's permanent magnets, automatically levitating it. The suspension is automatically and inherently stable – the closer the vehicle gets to the aluminum loops beneath it on the guideway, the stronger the levitating force. With appropriate design, Maglev vehicles using electrodynamic forces can be strongly stable in the vertical, horizontal, pitch, yaw, and roll directions, but able to move freely in the longitudinal direction along the guideway.

Electrodynamic Maglev can use either conventional permanent magnets or superconducting magnets. The conventional permanent magnets are much weaker in magnetic strength than superconducting magnets. As a consequence, Maglev vehicles that use permanent magnets have very small gaps between the vehicle and the guideway, on the order of 1 cm (3/8 in.) and are very limited in their capability to lift heavy weights.

In contrast, Maglev vehicles that use superconducting magnets have much larger gaps between the vehicle and the guideway, on the order of 10 cm (4 in.) or more, and have much greater weight-lifting capability. Moreover, they are inherently very strong, stable, and can be designed to resist hurricane force winds and strong earthquakes without contacting the guideway.

The technology for superconducting magnets is commercially well developed. There are thousands of superconducting MRI medical units all around the world, and superconducting magnets are widely used in R&D laboratories. The Large Hadron Collider (LHC) at the CERN Laboratory in Switzerland, for example, has 54 km (31 miles) of superconducting magnets, all of which must function perfectly for the LHC to operate. The same length of magnets on Maglev vehicles would provide half of the highway and airplane passenger miles in the USA, plus half of the intercity truck long distance miles.

Japan is now operating a first-generation passenger Maglev system in Yamanashi Prefecture that has carried well over 80,000 passengers, with accumulated running distances of hundreds of thousands of kilometers. Japan plans to extend their system to become a 500 km (300 miles) route between Tokyo and Osaka that will carry 100,000 passengers daily, with a trip time of 1 h.

Germany has developed a first-generation electromagnetic Maglev passenger system called Transrapid.

A commercial 31 km Transrapid system now operates between the center of Shanghai, China, and its airport.

An advanced second-generation superconducting Maglev system, termed Maglev-2000, is being developed in the USA. The basic components – quadrupole magnets, aluminum loop guideway panels, guideway beam and vehicle – have been fabricated and successfully tested, but as yet funds for operational testing at high speed on a guideway have not been available.

The second-generation Maglev-2000 system will have important new and unique capabilities beyond those already achieved by the present Japanese and German first-generation Maglev systems that will make it a major mode of sustainable transport in the rest of the twenty-first century. These new capabilities include:

- Transport of autos and trucks on Maglev vehicles, enabling electric vehicles to make long trips without the need to consume gasoline
- Much lower cost guideway system that can be privately financed and will not require government subsidies
- High speed electronic skip-stop switching of vehicles to off-line stations for unloading/loading operations enabling high average speeds with many closely spaced stations
- Ability to adapt Maglev-levitated travel to existing railroad tracks at very low cost, enabling Maglev travel inside urban and suburban areas without needing to build new infrastructure
- Ability to greatly reduce highway deaths and injuries by transporting people, autos, and trucks on Maglev rather than on highways
- Ability to use superconducting Maglev for other important applications, including low cost storage of electrical energy from variable wind and solar farms; the long distance, low cost transport of fresh water to drought areas; and very low cost for launching payloads into orbit, particularly space solar power satellites that can beam massive amounts of clean power down to Earth to meet power needs in an environmentally acceptable manner

The implementation of Maglev as a major mode of transport will enable much better sustainable living standards for the world's population, without environmentally damaging the planet by the massive use of fossil fuels.

Introduction

History and Impact of New Modes of Transportation

Over the last 200 years, the development of revolutionary new modes of transport have transformed human society, greatly raising the standard of living and enabling people to do things that were previously undreamed of.

Maglev, magnetic levitation, is such a revolutionary new mode of transport. It will dramatically change how humanity transports people and goods, launch payloads into space, store large amounts of electrical energy generated by wind and solar sources, and deliver billions of gallons of water over long distances to drought stricken regions. Moreover, it will be sustainable for the long term, and not require the use of destructive fossil fuels. In 1800, the only modes of travel were walking, horses, wagons, and sailing ships. In the USA, the per capita annual GDP was only $1,200 (in constant 2007 dollars) and the annual per capita travel distance was just 1,500 miles [1]. Today, the annual per capita GDP is $50,000 (in constant 2007 dollars) and the per capita annual travel distance is 15,000 miles [1].

What happened? A series of revolutionary new modes of travel that made it much faster, better, and cheaper to transport people and goods. During the Constitutional Convention, it took many days to travel from New England to Philadelphia, and to cross the ocean, many weeks. Even in the late 1800s, with steam boats and railroads, it took Phileas Fogg 80 days to go around the world.

The eight major transport revolutions initiated by the USA were (Fig. 1):

1. The Erie Canal (1814)
2. Steamboats on the Hudson and Mississippi (1807 and 1811)
3. The Transcontinental Railroad (1869)
4. The Panama Canal (1914)
5. Henry Ford and the Model T (1908)
6. The Wright Brothers and Kitty Hawk (1903)
7. The Interstate Highway System (1956)
8. The Moon Landing (July 20, 1969)

MAGLEV Technology Development. Figure 1
The eight American transport revolutions

Maglev will be an equally transforming new mode of transport. On Earth, it will move people and goods without being powered by fossil fuels that emit massive amounts of greenhouse gases and pollutants, in vehicles that are very safe, efficient, convenient, quiet, and comfortable. Maglev will also store large amounts of electric energy at very high efficiency and low cost, transport very large amounts of water for long distances over difficult terrain, and launch payloads into space at very low cost, including space satellites that can beam large amounts of power to the Earth.

Why Fossil Fueled Transport Is Not Sustainable

Today's Transport Systems – autos, trucks, airplanes, most trains, and ships – are critically important to present society and its standard of living. All are critically dependent on oil. Without oil, humanity would be back in the 1700s, with only horses and wagons and sailing ships.

Since Edwin Drake started pumping oil in Western Pennsylvania in 1859, the world has consumed approximately one trillion barrels of oil, most of it for transport. How much is a trillion barrels? Visualize a lake of oil that is one square mile in cross section containing a trillion barrels of oil. The oil lake would be 40 miles deep.

Another trillion barrels of oil is still in the ground, but it will not sustain the world for very long. World oil production has plateaued at about 30 billion barrels per year and will soon start to steadily decline. More significant than the arguments over when the "peak oil" crisis will occur is the "oil competition" crisis. As countries like China and India rapidly industrialize, competition with the developed countries for ever scarcer oil will drive up the price of oil. Today, highway traffic in China is increasing 18% annually, and more cars are sold per year in China than in the USA. Today (2010) oil costs about $80 per barrel; in a few years, analysts predict $200 per barrel.

For most of the rest of the twenty-first century, the present world transport systems will not be sustainable, using conventional oil for fuel.

Can society sustain existing autos, trucks, airplanes, trains, and ships with some alternative fuel as the oil runs out? Biofuels? Hydrogen? Synthetic fuels derived from coal, oil shale, tar sands, methane hydrates from ocean beds? No. None of these will be able to maintain society's present transport systems powered by the internal combustion engine. There are a variety of reasons why these alternative fuels are not practical on the scale needed to support a world population of nine billion people in 2050 (Fig. 2).

Biofuels? Not practical for the amounts needed. The acreage required is prohibitively large. In a world

MAGLEV Technology Development. Figure 2
The decision tree for future transport

where there is not enough arable land to adequately feed today's population of 6.6 billion people, which is projected to be 9 billion by 2050, biofuels can supply only a tiny fraction of future transport needs. Not only is the population growing, but the fertility of the world's arable land is declining, due to over use, erosion, increasing acidification due to excessive use of fertilizers, and increasing droughts. Humanity will be lucky to avoid massive famines in the years ahead, even if biofuels are not produced.

Hydrogen fuel would require 1,000 new nuclear reactors, each of 1,000 MW electrical capacity – ten times more than now operated in the USA – to make enough hydrogen fuel to equal the gasoline and diesel fuel currently consumed in USA's transport systems.

Hydrogen cars raise a serious security issue. Over one million cars are stolen in the USA per year. After stealing a hydrogen car, a terrorist need only attach a small bomb with an explosive-driven penetrator to the hydrogen tank, and then park it in a public parking garage, or shopping mall, or on a busy city street. The penetrator bomb could be then remotely detonated by cell phone or an attached timer, releasing the hydrogen gas to cause a massive explosion. Result? Many deaths with no way to prevent them. A terrorist would need no special skills. The penetrator bombs could probably be bought in the black market.

While more expensive than oil, synthetic gasoline and diesel fuel can be manufactured from coal, tar sands, oil shale, and methane at an acceptable cost. The reserves are enormous and could sustain oil-fueled transport for hundreds of years.

The problem with synfuels is not the sustainability of fuel supply, but sustainability of Earth's environment due to the release of carbon dioxide to the atmosphere from the manufacture of the synfuels, and the release of carbon dioxide from the tailpipes of the vehicles that burn the synfuels. Today, the US transport sector emits two billion tons per year of carbon dioxide into the atmosphere [2], roughly one-third of total US emissions. The carbon dioxide emissions from the manufacture of the synfuels needed to replace the oil now consumed by US transport would add another two billion tons per year to the atmosphere, for a total transport emission of four billion tons annually.

Would leaders call for a reduction of 80% in carbon dioxide emissions from today's levels, to be achieved by 2050? This corresponds to a total world emission of five billion tons annually in 2050. Four billion tons of just US transport emissions at today's level of transport would be four-fifth of the world's total.

With synfuels for transport, there is no way to reduce carbon dioxide emissions below today's level, even if all other present sources – coal-fired power plants, industry and home heating, etc. – were to go to zero. In fact, as the developing countries industrialize, their transport needs will greatly increase, making the world's total emissions from transport alone in 2050 much greater than today's total world emissions of 25 billion tons per year [3].

There is no practical way to capture the carbon dioxide emissions from autos, trucks, airplanes, trains, and ships. Inevitably, they will enter the atmosphere.
